*Where brick of larger or smaller sizes than the dimensions given above for blocks are to be tested, the same number of bricks per charge should be used, but allowance for the difference in size should be made in setting the limits for average and maximum rattler loss.

tificate of the operator, that the test was made under the specifications of the Am. Soc. Test. Mat., and that the record is a true record. (24) The signature of the operator or person responsible for the test. (25) The serial number of the test.

"In the event of more than one copy of the record of any test being required, they may be furnished on separate sheets, and marked duplicates, but the original record shall always be preserved intact and complete. For the convenience of the public, the accompanying blank form, which provides space for the necessary data, is furnished and its use recommended.

Report of Standard Rattler Test of Paving Brick

IDENTIFICATION DATA Serial No......

Name of the firm furnishing sample..
Name of the firm manufacturing sample..
Street or job which sample represents..
Brands or marks on the brick..
Quantity furnished.......................Drying Treatment........................
Date received.......................Date tested........................
Length.................Breadth..................Thickness..................

STANDARDIZATION DATA

Weight of Charge (After Standardization)	Condition of Lock Nuts on Staves	Condition of Scales	Number and Position of Fresh Stave-Liners	Repairs. (Note any repairs affecting the condition of the barrel)
10 Large spheres.... Small spheres. Total.........				

Number of charges tested since last inspection..

RUNNING DATA

	Time Readings			Revolution Counter Readings	Running Notes, Stops, etc
	Hours	Minutes	Seconds		
Beginning of Test.... Final Reading.......					

WEIGHTS AND CALCULATIONS

		Percentage Loss (Note: The Calculation Must Appear)
Initial Weight of Ten Bricks.......... Final Weight of Same............... Loss of Weight....................		

Number of broken bricks and remarks on same..................................

I certify that the foregoing test was made under the specifications of the American Society for Testing Materials, and is a true record.

(Signature of Tester) ....

Date.................... Location of Laboratory..............................

"Acceptance and Rejection of Material. 15. BASIS OF ACCEPTANCE OR REJECTION. Paving bricks shall not be judged for acceptance or rejection by the results of individual

tests, but by the average of not less than five tests. Where a lot of bricks fail to meet the required average, it shall be optional with the buyer, whether the bricks shall be definitely rejected or whether they may be regraded and a portion selected for further test as provided in Par. 16.

"16. RANGE OF FLUCTUATION. Some fluctuation in the results of the rattler test, both on account of variations in the bricks and in the machine used in testing, are unavoidable, and a reasonable allowance for such fluctuations should be made, wherever the standard may be fixed. In any lot of paving brick, if the loss on a test computed upon its initial weight exceeds the standard loss by more than 2%, then the portion of the lot represented by that test shall at once be resampled and three more tests executed upon it, and if any of these three tests shall again exceed by more than 2% the required standard, then that portion of the lot shall be rejected. If in any lot of brick, two or more tests exceed the permissible maximum, then the buyer may at his option reject the entire lot, even tho the average of all the tests executed may be within the required limits.

"17. FIXING OF STANDARDS. The percentage of loss which may be taken as the standard, will not be fixed in these specifications, and shall remain within the province of the contracting parties. For the information of the public, the following scale of average losses is given, representing what may be expected of tests executed under the foregoing specifications:

	General Average Loss Percent	Maximum Permissible Loss Percent
For bricks suitable for heavy traffic........	22	24
For bricks suitable for medium traffic......	24	26
For bricks suitable for light traffic..........	26	28

Which of these grades should be specified in any given district and for any given purpose is a matter wholly within the province of the buyer, and should be governed by the kind and amount of traffic to be carried, and the quality of paving bricks available.

"18. CULLING AND RETESTING. Where, under Pars. 15 and 16, a lot or portion of a lot of bricks is rejected, either by reason of failure to show a low enough average test or because of tests above the permissible maximum, the buyer may at his option permit the seller to regrade the rejected brick, separating out that portion, which he considers at fault and retaining that which he considers good. When the regrading is complete, the good portion shall be then resampled and retested, under the original conditions, and if it fails again either in average or in permissible maximum, then the buyer may definitely and finally reject the entire lot or portion under test.

"19. PAYMENT OF COST OF TESTING. Unless otherwise specified, the cost of testing the material as delivered or prepared for delivery, up to the prescribed number of tests for valid acceptance or rejection of the lot, shall be paid by the buyer. See also Par. 23. The cost of testing extra samples made necessary by the failure of the whole lot or any portion of it, shall be paid by the seller, whether the material is finally accepted or rejected.

" Visual Inspection. It shall be the right of the buyer to inspect the bricks, subsequent to their delivery at the place of use, and prior to or during laying, to cull out and reject upon the following grounds:

"20. All bricks which are broken in two or chipped in such a manner that neither wearing surface remains substantially intact, or that the lower or bearing surface is reduced in area by more than 1/5. Where bricks are rejected upon this ground, it shall be the duty of the purchaser to use them so far as practicable in obtaining the necessary half-bricks for breaking courses and making closures, instead of breaking otherwise whole and sound bricks for this purpose.

"21. All bricks which are cracked in such a degree as to produce defects such as are defined in Par. 20, either from shocks received in shipment and handling, or from defective conditions of manufacture, especially in drying, burning or cooling, unless

such cracks are plainly superficial and not such as to perceptibly weaken the resistance of the brick to its conditions of use.

"22. All bricks which are so off-size, or so misshapen, bent, twisted or kiln-marked, that they will not form a proper surface as defined by the paving specifications, or align with other bricks without making joints other than those permitted in the paving specifications.

"23. All bricks which are obviously too soft and too poorly vitrified to endure street wear. When any disagreement arises between buyer and seller under this item, it shall be the right of the buyer to make two or more rattler tests of the brick which he wishes to exclude, as provided in Par. 2, and if in either or both tests, the bricks fall beyond the maximum rattler losses permitted under the specifications, then all bricks having the same objectionable appearance may be excluded, and the seller shall pay for the cost of the test. But if under such procedure, the bricks which have been tested as objectionable, shall pass the rattler test, both tests falling within the permitted maximum, then the buyer cannot exclude the class of material represented by this test and he shall pay for the cost of the test.

"24. All bricks which differ so markedly in color from the type or average of the shipment, as to make the resultant pavement checkered or disagreeably mottled in appearance. This Section shall not be held to apply to the normal variations in color which may occur in the product of one plant among bricks which will meet the rattler test as referred to in Pars. 15, 16 and 17, but shall apply only to differences of color which imply differences in the material of which the bricks are made, or extreme differences in manufacture."

10. Cost Data on Brick

Table IV.—Production and Cost of Paving Brick in the United States

From *Mineral Resources of the United States, 1915*

Year	Quantity	Value	Average Price per Thousand
1895	381 591 000	$3 130 472	$8.20
1896	320 407 000	2 794 585	8.72
1897	435 851 000	3 582 037	8.22
1898	474 419 000	4 016 822	8.47
1899	580 751 000	4 750 424	8.18
1900	546 679 000	4 764 124	8.71
1901	605 077 000	5 484 134	9.06
1902	617 192 000	5 744 530	9.31
1903	654 499 000	6 453 849	9.86
1904	735 489 000	7 557 425	10.28
1905	665 879 000	6 703 710	10.07
1906	751 974 000	7 857 768	10.45
1907	876 245 000	9 654 282	11.02
1908	978 122 000	10 657 475	10.90
1909	1 023 654 000	11 269 586	11.01
1910	968 000 000	11 004 666	11.37
1911	948 758 000	11 115 742	11.72
1912	911 869 000	10 921 575	11.98
1913	958 680 000	12 138 221	12.66
1914	931 324 000	12 500 866	13.42
1915	953 335 000	12 230 899	12.83

CONSTRUCTION

11. Cushions

A cushion between the paving brick and the artificial foundation, unless the latter is of the proper quality of sand, has been considered necessary for two reasons: First, to offset and eliminate the unavoidable inequalities and unevennesses in the surface of the artificial or natural foundation; and

second, in order to give a uniform bearing and cushioning to, and to compensate for the inevitable inequalities in height of, the individual brick. Also it has been contended that there was a desirability for the interposition of a somewhat resilient layer between the rigid brick wearing surface and its equally rigid foundation, in order that a resiliency in the whole result might be secured to some extent at least, as well as to decrease the resonance and noise. All are not in agreement on these points and the effectiveness of the sand cushion.

Mortar Beds on top of the artificial foundation are a relatively new development in brick paving work, tho they have been used for wood blocks for many years, especially in Europe. In 1906, Baltimore laid a vitrified brick pavement on Lexington St. between Calvert and Charles Sts., using a ½-in layer of one part cement mixed with three parts sand, and since that time has laid several other streets with brick on a similar bed, altho the proportion of sand has been increased in some cases to five. In 1910, the roadways in the Penn. R. R. Terminal in New York City were similarly built with a mortar bed for the brick. Both the instances cited now show entirely satisfactory results from the use of the mortar bed. It is true that in each case, traffic conditions are peculiar. The 7% grade and the local police regulation making it a one-way street, limit the traffic on Lexington St., Baltimore, and the traffic on the Penn. R. R. Terminal roadways is preponderatingly that of rubber tired motor vehicles. Altho many other instances of the more recent use of mortar beds for brick pavements may be found, definite conclusions have not been drawn as yet. The use of mortar beds in substitution for a sand or other cushion may prove to be highly advantageous for many reasons, such as the elimination of hollow sounds or roaring in brick pavements, the successful correction of the tendency of a sand cushion to shift its place, greater ease and rapidity in construction, no increase and perhaps even a decrease in cost, and the result of an even more highly resistant surfacing. On the other hand, this substitution may result in increased resonance, increased rigidity and brittleness of surfacing, and increase in the effects of expansion and contraction. Cracking of the foundation may become apparent in the pavement when otherwise it would not be transmitted to the surfacing. See (15), (19), (22c), (30b), (31a), (32a), (32b), (35a), (35b), (43), (46), (47b), (49a), (49b), (52a) and (56).

With Sand Cushions, such as have been usually provided for brick pavements, the thickness for the cushion recommended by the National Paving Brick Manufacturers' Assn. is 1½ in after compaction. Some engineers reduce this figure going as low as 1 in, but unless the surface of the foundation is extremely and unusually even, a 1-in sand cushion is likely to prove unsatisfactory. While 1 in of sand will probably provide sufficient cushioning effect for the brick, less than 1 in will not do so. A 1-in cushion being specified and attempted, it is almost impossible to prevent the cushion having a thickness of less than 1 in at certain points, which points later prove foci of failure in the pavement surface.

It has been found, upon inspection, that under the peculiar conditions of some cases, a shifting of the sand cushion under the brick has taken place, and the brick have been in these cases left unsupported or unevenly supported in areas of the pavement. The thicker the cushion originally provided, the greater the probabilities of such possible shifting of the cushion, hence the maximum limit of 2 in. More than 2 in cannot be properly compacted. The shifting of the sand cushion is considered re-

sponsible for the objectionable hollow sound or resonance of some brick pavements.

A great deal of care, more than is usually displayed in the work of providing this cushion, is desirable. It should be of the greatest possible uniformity both as to composition and thickness. The sand should be free from pebbles and sufficiently free from loam or earthy matter to prevent its caking. See (20). It must be evenly spread and thoroly and evenly compacted. It cannot be spread properly if wet, and it cannot be evenly compacted if spread from dumped piles whose tops have been merely knocked off. A thoro raking of the cushion after spreading is desirable in order to secure an even distribution of the sand, and rolling is necessary to insure proper compaction. A template properly made and operated is then necessary for truing the surface of the cushion and securing the desirable evenness to it. Uniformity of thickness of the cushion is largely dependent upon the evenness of the surface of the foundation. The escape of the sand cushion into the joints of the artificial foundation along rails should be made impossible.

Sand Mixed with Bituminous Material is much more resilient than the sand alone. The use of this mixture may avoid some of the difficulties with sand cushions, and the thickness of the cushion might be cut down without loss of cushioning effect. Such a cushion would also be probably less likely to respond to shifting influence.

Sawdust Mixed with Bituminous Cement will form an elastic cushion, and one perhaps less expensive in certain localities than a sand mixture. The thickness necessary for cushioning effect in this case might be still further reduced. The bituminous cement might be expected to prevent the decay of the sawdust, and, if of proper quality and mixed in proper proportions, the resistance of the cushion to shifting influences would probably be at least normal.

Fibered-Asphalt Pavement might be used advantageously. Fibered-asphalt is a mixture of asphalt cement and wood fiber obtained as a by-product in the extraction of sap products from trees, the wood fibers in the process being of considerably greater length than the particles of sawdust.

The Cushion Should Always be Well Rolled. After spreading, to a slight excess in thickness, the sand and thoroly raking it, so as to secure an even disposition of it, a roller weighing from 300 to 400 lb should be drawn by hand both longitudinally and laterally or diagonally over the sand cushion. Any depressions resulting should be filled with more sand and the rolling resumed and continued until the utmost compaction of the sand is evenly secured. The surface of the sand should then be found to be slightly higher than the elevations desired for it, and it should be brought evenly to the proper height by striking off the surface with a template.

Specifications for Cushion Materials adopted at the First Conference, 1917, State Highway Engineers and Chemists, are as follows:

"The Sand shall pass a .... inch laboratory screen, and less than .... percent shall pass a 20-mesh sieve. The material removed by the elutriation test, consisting chiefly of clay and loam, shall not exceed .... percent by weight.

"The Granulated Slag shall consist of clean, sharp, gritty particles of water-cooled (insert types allowable) slag, all of which shall pass a .... inch laboratory screen."

12. Laying and Rolling the Brick

The usual practice is to lay the brick in courses at right angles with the axis of the street and on edge, so that the individual brick present to wear one of the two faces about 3½ by 8½. Exceptions to this practice

are sometimes met with at intersections where the courses in each quarter of the intersection are laid parallel to a diagonal thru the intersection with the idea of giving a better foothold to animals turning the corner or crossing the pavement. It has been suggested that no real necessity exists, when the pavement is properly grouted with cement mortar, for courses across the roadway and that the avoidance of gores in the surface of curved roadways may be had by laying the brick lengthwise. This has been successfully done in some cases. One of the difficulties in laying a brick pavement arises from the desirability of keeping the courses reasonably straight, for appearance's sake, and the joints between the courses and between the individual brick uniform, so as to permit evenness in their filling. The usual variation from the straight line allowable in the courses is within 2 in, for the attainment of its appearance, but it is not desirable to have the brick more tightly jammed together at some points than at others. Too wide a joint is obviously undesirable and too narrow a one is equally so because of the difficulties of properly filling excessively narrow joints. Different devices have been adopted for keeping the bricks at a certain distance from each other in the shape of letters or raised projections on the brick. The more recent device of lugs seems to give the best results and to provide for a proper width of joint.

Inspection of Brick During Laying. As brick samples to be tested are usually taken in the proportion of one sample for each 1000 brick in the shipment, it is evident that there is a considerable opportunity for individual brick of varying quality passing the tests. The presence of such brick in the pavement may result in uneven wear and the production of serious holes in the surface. It is frequently the practice, after the brick have been laid in the pavement, but before they are grouted, to sprinkle the pavement with water. The eye is then able to note quickly any great variation in the imperviousness of the individual brick, and the removal and replacement of these can quickly and readily be made. A very common practice under recent specifications consists of inspecting the brick after laying, but before filling the joints, and turning over, with the aid of a pair of tongs, those brick which have been placed in the pavement with an objectionable face up. This is bad practice, because the sand cushion is disturbed in the process. The best practice is to place the brick for the pavers so that they will invariably lay the brick with its best face up.

Bricks Laid on the Flat Side. A recent experiment has been made in a number of instances by laying the brick on their flat or larger side, and in courses as above. This departure gives the advantage of requiring slightly less brick per square yard than where they are laid on edge, tho it reduces the resistance of the pavement to sustaining heavy loads, and there is more liability of the brick becoming cross-broken thru the reduction in depth. There seems to be no good reason why the practice of laying the brick on their flat sides should not be followed where the loads coming on the pavement are only moderately heavy and where a proper foundation and cushion have been provided. The reduction in first cost per square yard by laying the brick flatwise would average between 5 and 10 cents per sq yd. Where the traffic is expected to be light, the laying of the brick flatwise may have another advantage, if a natural foundation of suitable sand is expected to be sufficient, in that the greater bearing area of the brick laid flatwise should reduce a tendency of the individual brick laid edgewise to become driven down under traffic. See (17), (30a), (30e), (54a) and (57).

The Brick Should be Rolled subsequent to laying and after the surface of the partly completed pavement has been swept clean, inspected for defects and the latter corrected. Disturbance of the brick after rolling should be avoided just as far as possible. The roller for the brick should be one that can be easily and rapidly managed and should weigh between 4 and 5 tons. In order to offset any tendency of the brick to careen under the roller, the number of forward trips of the latter over any part of the pavement should be equalled by the number of backward trips over the same part. The rolling should proceed beginning at each edge of the pavement along the curb and working toward the center of the roadway; then cross rolling at angles of about 45° each way from the center line; again rolling lengthwise and again cross rolling as before, continuing this process until the brick are firmly fixed in the cushion, the surface of the pavement even at the elevations intended and any inequalities of the cushion or in the height of the brick ironed out and the cushion more or less pushed up into the joints between the brick. This condition is always found in the case of properly rolled brick pavements, the rising of the cushion into the joints being somewhat uneven, in an amount varying from ½ to 1 in according to the conditions. Rolling with a horse roller or too heavy a steam roller can but result unsuccessfully, as under such rollers, the brick will invariably creep under the horizontal strains. Again, such rollers cause the brick to tilt as they are passed over and become displaced to an extent that the surface of the pavement becomes rougher the more it is rolled. Further, under excessive weights of roller, the brick are so pushed down that they rebound when the weight passes off and compaction to the desired degree is never secured.

After the brick are properly rolled and fixed, those that have broken under the roller should be removed and replaced, the new brick being carefully tamped into place. In places where the use of the roller is impracticable, such as around manholes or close to the curbs, the brick should be brought to a true surface and made firm by means of ramming. For this purpose, a rammer should weigh from 80 to 100 lb and its blows should not fall directly upon the brick but should be transmitted thru a board laid on their surface.

13. Joint Filling

The Filler Recommended by the National Paving Brick Manufacturers' Assn. is Cement Grout, except for expansion joints. The cement filler when properly applied unquestionably gives additional strength to the pavement by uniting the individual brick together into a strongly coherent mass, and thus enabling the distribution of the strains over a larger area. It gives better protection to the edges of the individual brick and against their tendency to spall at the edges under blows. It aids toward uniformity of wear and results in a smoother surface for the pavement. Its disadvantages are the mechanical difficulties of properly applying a cement filler and of having this sort of filling sufficiently uniform thruout the paved area. The cement filler is rigid and increases, rather than decreases, the rigidity of the pavement and the effects of expansion and contraction. On steep grades, the cement grouted brick pavement may be objectionably slippery, especially in certain kinds of weather. It is objected to frequently as producing a more noisy pavement than a bituminous filler, but this complaint is disputed (see Art. 2).

The Relative Strength of Cement Grout Fillers made with different

proportions of cement and sand is indicated by some tests made in connection with some brick pavement work in King County, Wash.

Allen (11) states that these tests were made "of sections of brick pavement constructed as beams 12 in wide and spanning 42 in between supports, chiefly to study the efficiency of cement joints mixed 1 : 1, 1 : 1½, and 1 : 2. In making these beams, the methods of laying and of mixing and brushing in grout commonly used in county work were those employed. Each beam was tested on a 42 in span, center to center, and the load applied at the center of the span. The beams were placed in the testing machine with the wearing surface up, on which surface the load was applied. The ends of the beams rested on rocker supports, and plaster of Paris was used to secure an even bearing at all contact points. A deflectometer was used to record the amount of deflection in the beam at the instant of failure. With the 1 : 1 grout the plane of failure cut right across one brick and for the rest of the way was thru the bond. In one instance a lug was sheared off. With the 1 : 1½ grout the failure in one case was across two brick and the rest of the way thru the bond. In the second case the failure was thru the bond all of the way. With the 1 : 2 grout the failure was entirely thru the bond in each instance. In no instance was the failure thru the grout; it was always thru the bond, across the grout or thru the brick. The results of these beam tests are given in Table V:

Table V

Beam No.	Dimensions of Beams			Deflection at Max. Load Ins	Maximum Load Pounds	Modulus of Rupture, lb per sq in	Cement Sand Mixture	Number of Bricks Ruptured

The Application of the Cement Filler is one of the most important features of proper brick pavement construction and should have the utmost care. The cement filler should be mechanically mixed and mechanically applied, if possible. While in the application of the cement filler, usually more incorrect and varied means or methods are resorted to than in any other portion of the work, the proper method is a simple one and easily followed. Clean sand, first-class Portland cement and a proper proportion of water are necessary. Too much water is as objectionable as too little, owing to the greater tendency toward segregation of the sand and cement when water is used in excess. Too little water does not provide the fluidity necessary for the mixture to properly enter the joints. A good method for applying the cement filler to brick pavements, which method has been developed thru practical work, has been carefully described in the publications of the National Paving Brick Manufacturers' Assn. as follows:

"The sand should be dry. The mixture, not exceeding 1/3 bu of the sand, together with a like amount of cement, shall be placed in the box and mixed dry, until the mass assumes an even and unbroken shade of color. Then water shall be added to form a liquid mixture of the consistency of thin cream. From the time the water is applied until the last drop is removed and floated into the joints of the brick pavement,

the mixture must be kept in constant motion. The mixture shall be removed from the box to the street surface with a scoop shovel, all the while being stirred in the box as the same is being thus emptied. The box for this purpose shall be 3½ to 4 ft long, 27 to 30 in wide, and 14 in deep, resting on legs of different lengths, so that the mixture will readily flow to the lower corner of the box, which should be from 8 to 10 in above the pavement. This mixture, from the moment it touches the brick, shall be thoroly swept into the joints. Two such boxes shall be provided in case the street is 20 ft or less in width; exceeding 20 ft in width, three boxes should be used.

"The work of filling should thus be carried forward in line until an advance of 15 to 20 yd has been made, when the same force and appliances shall be turned back and cover the same space in like manner, except to make the proportions ⅔ Portland cement, and ⅓ sand. To avoid the possibility of the thickening at any point, there should be a man with a sprinkling can, the head perforated with small holes, sprinkling gently the surface ahead of the sweeper. Within ½ to ¾ hr after this last coat is applied, and the grout between the joints has fully subsided and the initial set is taking place, the whole surface must be slightly sprinkled and all surplus mixture left on the tops of the brick swept into the joints, bringing them up flush and full. After the joints are thus filled flush with the top of the brick and sufficient time for evaporation or initial hardening has taken place, so that the coating of sand will not absorb any moisture from the cement mixture, ½ in of sand shall be spread over the whole surface, and in case the work is subjected to a hot summer sun, an occasional sprinkling sufficient to dampen the sand should follow for 2 or 3 days.

"The first application should be thin in order that it may flow to the depth of the joints of the brick, thereby insuring a substantial bond, and should be kept in constant motion while being applied, otherwise the sand will settle, leaving water and cement, instead of water, sand and cement. The water and cement would not be objectionable, but the sand by itself is wholly so.

"It must also be mixed in small quantities, as it is next to impossible to keep the sand in suspension when more than a common water pail of each, sand and cement, is used, and unless it is deposited upon the pavement with the sand in combination with the solution, the cement and water will get into the lower portion of the joints between the bricks, and the sand without the cement in the upper portion. It is preferable, after the sand and cement have been mixed dry, to apply sufficient water and mix slowly, first to a good mortar, then add sufficient water to bring the mortar to the required consistency. By this method a more thoro adhesion of the cement to the sand can be obtained."

Specifications for Grouting Sand adopted at the First Conference, 1917, State Highway Engineers and Chemists are as follows:

"The sand shall consist of clean, hard, durable, uncoated particles, preferably siliceous, free from lumps of clay and all organic matter.

"**Grading.** It shall be well graded from coarse to fine and, when tested by means of laboratory screens, shall meet the following requirements:

Passing ....* mesh sieve................not less than ....**%.
Passing 100-mesh sieve................not more than ....%.
Not more than ....% by weight shall be removed by the elutriation test.

"**Mortar Strength Test.** When the sand is mixed with Portland cement in the proportions of 1 part of cement to 3 parts of sand by weight, according to standard methods of making 1 : 3 mortar briquets, the resulting mortar at the age of 7 and 28 days shall have a tensile strength of at least .... ***percent of that developed in the same time by mortar of the same proportions and consistency, made of the same cement and Ottawa sand. Preliminary acceptance samples shall be subjected to both 7 and 28-day tests, and acceptance based thereupon. Samples tested during the progress of the work will be accepted on the basis of the 7-day test."

The Following Practices Often Observed are Erroneous and should be avoided: The filler is applied from the mixing box with a bucket and

*It is recommended that a 10-mesh sieve be specified.
**Ninety-five percent is recommended for this purpose.
***It is recommended that 65 percent be the minimum allowable strength ratio; and that in localities where practicable, a higher strength ratio be specified.

carried to the point of application. Settlement of the sand to the bottom of the bucket invariably occurs, as it also does when too great a time elapses between the mixing in the box and the turning of the box or the emptying of the box, especially if the stirring is not continuous. Water, applied to the dry mixture before the latter has reached an even shade, interferes with the proper adhesion of the particles. Remedying an improper thickness of mixture by throwing it upon the pavement and then adding more water serves only to float the cement away from the sand. Applying the mixture to the pavement faster than it can be swept in results in lack of uniformity and dissatisfaction. If the quantity of mixture applied requires a portion of it to be swept to a considerable distance in order for it to disappear in the joints, the last that goes in will be little better than pure sand. By the proper method, the mixture in the box is drawn to the upper portion of the box by two workmen with hoes, and with the natural backward flow, the mixture is equally agitated. The lift of the scoop, with the box sufficiently adjacent to the joints to be filled, will allow a mixture in proper condition to strike the surface of the brick and to immediately enter the joints, thus more nearly insuring the filler in place in its proper proportion than by any other method. By the use of a sufficient number of boxes and a systematized force of workmen, the greatest economy to the contractor is secured and the possibilities of the cement filler attained.

Dampening the Brick ahead of the application of the filler is necessary in almost all cases in order that proper adhesion of the filler to the brick shall be had. The brick must be uniformly dampened and not excessively wetted. The use of a hose, especially one throwing a stream of water, is objectionable for this purpose. It may be possible to use a hose satisfactorily if it is supplied with a nozzle which will result in a thin spray of water being thrown thru it. Even then, the use of the hose tends to result in the application of too much water. A sprinkling can with what is known as a rose head, that is, a head with many small perforations in it over the spout, and the careful application of the water by hand should generally be required. See (30d).

Bituminous Fillers reduce the necessity of expansion joints in the pavement, and permit a certain flexibility in the pavement which practically obliterates any cracking of the brick thru contraction or expansion. They are usually applied with greater ease and uniformity than in the case of a cement filler. They leave a surface to the pavement which is less smooth and consequently less slippery. Another advantage claimed for the bituminous filler is the possibility when once cracked, of its reunion, which is impossible in a cement filler. Their disadvantages are that the proper kind of bituminous filler is usually difficult to obtain for any specific case; that is, bituminous cement, with the proper quality of adhesiveness in order to stick the brick together, is generally quite susceptible to extremes of heat and cold, becoming fluid and running out of the joints on grades in the warm sun, and becoming brittle and breaking in the joints in cold weather. Any lack of imperviousness in the joints, thru the breaking of the filler, will result disastrously to the cushion and to the pavement. Further, bituminous fillers fail to support the edges of the brick sufficiently to prevent spalling, and it is but a short time after a brick pavement with bituminous joints is completed before the brick begin to wear into convex form on their upper surface, thus increasing the difficulties of keeping the pavement thoroly clean, increasing the noise from the surface, and damaging its appearance.

14. Expansion Joints

Expansion joints should be provided, along the curbs at least, in all brick pavements. In the case of cement grouted brick pavements, greater provision for expansion joints must be made than in the case of brick pavements with bituminous joints. A general practice, where the brick are laid in courses across the roadway, is to place a board of a proper thickness next to the curb before the brick are laid and then, after the joint filling of the pavement is completed, to withdraw the board and fill the space left with a bituminous cement. The thickness of the board to be used will depend upon the width of the street, and the following thicknesses are those recommended by the National Paving Brick Manufacturers' Assn.: Width up to 20 ft, ½ in along each curb; 20 to 30 ft, 3/4 in along each curb; 30 ft or over, 1 in along each curb.

Distribution of Total Thickness of Bituminous Filler. A better practice is to distribute the thickness of this expansion joint over three or four joints in courses of brick laid parallel to the curb and against which longitudinal courses, the courses of the brick across the roadway abut. This is especially so in the cases of the wider expansion joints required. There is less likelihood of the several thinner joints being rendered ineffective by sand, gravel or other debris from the roadway, than in the case of one wide joint.

Expansion Joints Across the Street are now generally omitted and are recommended to be always omitted by the latest specifications of the National Paving Brick Manufacturers' Assn. It is questionable if in the cases of wide brick pavements, this reçommendation should be followed for the reason that, on some streets laid in recent years under the modern specifications and the most careful inspection, it has been found that apparently the strains caused by expansion in the cement grouted brick pavements have not all been transmitted to the expansion joints on the side and there taken up without causing some shattering of the brick in the pavement apparently thru excessive pressure on these brick. In the cases referred to, the streets were 40 ft or more between curbs and no street car tracks were in the area of the pavement. The only expansion joints were the ones provided along the curbs. The crushing strength of the brick, altho normal at least, was apparently insufficient to resist the strains, caused by expansion or contraction, which passed thru them from large adjacent areas. Apparently expansion joints at intervals of, say, 100 ft across the street would have obviated the difficulty.

Transverse Expansion Joint for Monolithic Brick Paving (48a). "The transverse joint has a special feature that is original with the writer. When the location of the joint is made, a trench 2 ft wide, 12 in on each side of the location, is cut to a depth of 3 in. This trench is filled level full with concrete and covered with building paper. The concrete base is then placed and shaped over this support. The joint is afterward cut thru to the paper and filled with sand, as above described, care being taken not to break the paper. This gives a solid base for the joint to rest upon, and on which it may freely move. This prevents settling of the base, which might be caused from water seeping thru and softening the subgrade at these joints. Another special feature of the joint is the laying of the brick as headers, with the prepared joint between the heads. Laying the brick as headers at the end of all street intersections, which takes the place of marginal curbing, is another special feature. The theory for this arrangement is that the weakest point in the pavement, and the point most exposed to traffic, is at the joints and at the end of the intersections. By laying the brick as headers a longer bearing is given for resisting the impact from vehicles and from horses' hoofs."

Precautions in Construction of Expansion Joints. Great care must be taken with the expansion joints in order that there may be no hindrance

to their acting as such. Sand or other incompressible material of any kind must not be allowed to enter them and the bituminous cement must be of the proper quality to permit the movement of the brick adjacent without separation either from the brick or in the bituminous cement itself. Any such separation will permit the entrance of foreign material and ultimately destroy the expansibility of the joint. The bituminous cement must not be so susceptible to heat as to run out of the joints in hot weather nor so susceptible to cold as to permit the separation of the brick from the bituminous cement or the cracking open of the bituminous filler in the joints during the contraction of the pavement. If the bituminous cement is likely to be covered with water for considerable periods at certain seasons, its good qualities must not be affected by this immersion, and if the expansion joints are so situated as to receive the shocks of traffic, it must not at any time become brittle enough to be broken out of the joints by the traffic. The main objections to expansion joints in the pavement across the roadway are their cost and their interference with uniformity of the surface exposed to traffic and the resulting ridge or depression which will occur at them and tend toward uneven wear.

Where Car Tracks Are to Exist within the area of the brick pavement, an expansion joint should be provided along both sides of each rail. It may be placed next to the rail or rail filler block, or it may be installed along the side of the runner, block laid lengthwise with the rail, in case the latter is used.

15. Specifications for Construction

Fundamental Principles adopted in 1917 by the Spec. Com. Mat. Road Cons., Am. Soc. C. E. (12b).

"**Artificial Foundation.** Owing to the inelastic nature of brick and slag block pavements, the surface of the wearing course must be smooth and true to contour, to insure ease of traction, comfortable riding, and the integrity of the surface, particularly where cement joints are used. Special care, therefore, should be taken to provide a concrete foundation of ample strength and with a surface parallel with that of the wearing course. The minimum of 4 in for the thickness of the artificial foundation should be used only when the brick or blocks are bedded in cement mortar on a concrete foundation resulting in a monolithic pavement approximately 8 in in thickness, or when the natural foundation affords good drainage and is firm and unyielding. There may be conditions under which the concrete foundation can be entirely dispensed with, but this is only justified where, owing to the low first cost of the brick, exceptionally good bearing qualities of the soil, light traffic, and lack of funds to provide a more substantial road surface, brick laid with sand joints and without an artificial foundation may be used as the first step in road improvement. If the roadway is not kept clean, the material which accumulates on the surface of the wearing course will protect it from injury, and its function will then be simply to provide a foundation for an earth road.

"**Cushion Course.** The function of the cushion between the brick or block and the artificial foundation of concrete is to give resiliency to the wearing course and to allow for irregularities in the surface of the concrete and for unavoidable variations in the depth of the brick or block. If the surface of the concrete foundation is made true to the adopted cross-section, as the variation of the depth of the brick or block decreases, the thickness of the sand cushion may be correspondingly decreased. The desirable resiliency will be secured by a sand cushion 1 in, or even slightly less, in depth, provided that depth is uniform, and if the surface of the concrete foundation is truly parallel with the finished pavement; and, if the variation in the depth of the brick or block does not exceed ⅛ in, the thickness of the sand cushion can safely be reduced to ¾ in. In a number of brick pavements recently laid, the cushion course has been dispensed with entirely, the brick having been bedded in cement mortar spread over the concrete foundation. This results in a monolithic structure less capable of absorb-

ing shock than is the case where a sand or bituminous cushion is interposed between the wearing surface and the foundation, and the joints are filled with a bituminous filler. A cushion course composed of sand or stone chips and a bituminous cement from 1/4 to 1/2 in in thickness may be substituted for sand or cement mortar, provided the surface of the concrete foundation is made sufficiently smooth and regular in contour.

"Construction. The brick or block should be laid in straight courses at right angles to the axis of the roadway, altho at intersections they may advantageously be laid in diagonal courses arranged so that traffic turning any of the corners will move across and not along the continuous joints. They should be laid so that the joints shall be uniform in width and of sufficient width only to permit the filler to reach the bottom of the joints. Lug bricks have the advantage of insuring such uniform joints, with ordinary care in laying. If a sand cushion is used great care should be taken to avoid any disturbance of the surface of the cushion after it shall have been brought to true grade by using a template. If bedded in a mortar or bituminous cushion, the brick or block should be bedded so that the surface shall be as true as possible. In all cases the brick after being laid should be brought to a true and even surface by the use of a roller."

Specifications for Brick Pavement with Sand Cushion as adopted in 1916 by the Am. Soc. Mun. Imp. are as follows, except that the description of the rattler test (see Art. 9) is omitted.

"Character of Brick. All brick must be of the sizes commercially known as paving brick the widths of which must not vary more than 1/8 in. They must be thoroly annealed, tough and durable, regular in size, shape and evenly burned. When broken, the brick shall show a dense, stone-like body, free from lime, air-pockets, cracks or marked laminations. They must not be fire flashed, smoked or treated in any manner tending to give artificially a uniform color outside. Kiln marks must not exceed 3/16 in one from another, and one edge at least shall show but slight kiln marks. All brick so distorted in burning as to lay unevenly in the pavement shall be rejected.

"The STANDARD SIZE of paving brick shall be 3 1/2 in in width, 4 in in depth, and 8 1/2 in in length. They shall not vary from these dimensions to exceed 1/8 in in width and depth, and not more than 1/2 in in length. If the edges of the brick are rounded the radius shall not exceed 3/16 in. Only brick with four raised lugs on one side not to exceed 1/4 in nor less than 1/8 in in height shall be used. No one lug shall exceed 1/2 in in area.

"Inspection of Brick. All brick shall be subject to thoro inspection before and after laying and rolling, and all rejected material shall be immediately removed from the street. Factory inspection of brick, including the rattler test, shall be made if, in the judgment of the engineer, it be expedient. This test and inspection, however, in no wise prevent further tests and inspection of the brick after they have been received upon the improvement, if in the judgment of the engineer such is warranted.

"Delivery of Brick. The brick shall be hauled and carefully unloaded by hand without spalling or otherwise damaging the brick, and neatly piled on the walks or outside of the curbs before the grading is finished, and in laying be carried from there to the pavement.

"Rattler Test for Block Size. The brick shall not lose of their weight more than 22% after being submitted to the following tests, provided, however, that brick from any one factory and used in any one improvement shall not vary more than 8 points. Samples of brick of uniform shape and appearance shall be taken from each car tested, estimated at 10 000 brick. Brick having a defect, that would cull them, shall not be used. Three grades of samples shall be tested, one of the softest, one of the medium and one of the hardest burned. If all of the tests over-run the above percentage of loss, the car shall be rejected. If one or two of the tests over-run, another test of said grade or grades shall be made. Should only one of these tests over-run the specified percentages of loss, the contractor may cull said grade, provided they do not exceed 10% of the amount of brick in the car, and deliver the balance on the improvement. Otherwise the whole car will be rejected. In order to prevent the continued shipments of inferior brick, only two cars to two separate shipments of any make of brick will be tested. Should they fail to meet the requirements stated above said make of brick will be rejected for this improvement.

"NUMBER AND CONDITION OF BRICK. Ten paving brick shall constitute the number to be used in a single test. The brick shall be thoroly dried for at least 3 hr in a temperature of 38° C (100° F) before testing.

"TESTS BEFORE UNLOADING. The contractor shall notify the proper city official of the location and car number of each carload of brick received, so that samples, if deemed necessary, may be taken and tested by the city, and no brick shall be delivered on or adjacent to any improvement on which brick are to be used until a written statement has been received from the Engineer or his authorized representative, that they have been superficially inspected or have passed the required tests. Decision relative to each carload will be made within 24 hr of notice. Permission to deliver brick on the line of work shall not be considered a final acceptance in any respect.

"Foundation. The cement used shall conform to the requirements specified. The fine aggregate shall consist of any material of siliceous or igneous origin, free from mica in excess of 5%, and other impurities, uniformly graded, the particles ranging in size from ¼ in to that which will pass a 100-mesh sieve. The coarse aggregate shall be sound gravel, broken stone or slag, having a specific gravity of not less than 2.6. It shall be free from all foreign matter, uniformly graded, and shall range in size from ¼ in up, the largest particles not to exceed in any dimension one-half the thickness of the concrete in place.

"In preparing the concrete, the cement and aggregate shall be measured separately and then mixed in such proportions that the resulting concrete shall contain fine aggregate amounting to one-half of the volume of the coarse aggregate, and that 7 cu ft of concrete in place will contain 94 lb of cement. The ingredients of the concrete shall be thoroly mixed, sufficient water being added to obtain the desired consistency, and the mixing continued until the materials are uniformly distributed, and each particle of the fine aggregate is thoroly coated with cement, and each particle of the coarse aggregate is thoroly coated with mortar. When a mechanical concrete mixer is used, the materials must be proportioned dry, and then deposited in the mixer all at the same time. The mixer must produce a concrete of uniform consistency and color, with the stones thoroly mixed with water, sand and cement. The materials shall be mixed wet enough to produce a concrete of a consistency that will flush readily under light tamping, but which can be handled without causing a separation of the coarse aggregate from the mortar. Retempering, that is, remixing with additional water, mortar or concrete that has partially hardened, will not be permitted.

"The concrete shall be deposited in a layer on the subgrade in such quantities that, after being thoroly rammed in place, it will be of the required thickness, and the upper surface shall be true, uniform and parallel with the surface of the finished pavement. In conveying the concrete from the place of mixing to the place of deposit, the operation must be conducted in such a manner that no mortar will be lost and the concrete must be so handled that the foundation will be of uniform composition thruout, showing no excess nor lack of mortar in any place.

"The foundation shall be 6 in in thickness, with its upper surface finished parallel to and 5½ in below the grade of the finished pavement.

"When complete, the foundation shall be kept moist for not less than 2 days and it shall be protected from traffic until the concrete has thoroly set.

"No concrete shall be mixed while the air temperature is below 0° C (32° F), and in no case shall any material containing frost be used, and if this temperature is reached at any time before the foundation shall have been thoroly set, it shall be immediately provided with such covering as will protect it from all damage. In no event shall a concrete foundation be laid on a frozen subgrade.

"Sand Cushion. Over the foundation, which must be thoroly cleaned, shall be spread to a uniform depth of 1½ in, after rolling, a cushion of clean, sharp sand, free from foreign matter except that it may contain not to exceed 5% of loam. The sand must be fairly well graded from ¼ in to that which will be retained on a 50-mesh sieve. The word sand includes broken stone or slag meeting the specified grading. The cushion shall be carefully shaped to a true cross-section of the roadway by means of a template having a steel faced edge, covering at least one-half the width of the brick work, and so fitted with rollers as to be easily drawn on the curb and guide timbers or rail.

"The TEMPLATE shall be built in substantial accordance with plan accompanying these specifications.

"GUIDE TIMBERS shall be 1½ by 4 in by 16 ft, dressed on two sides, laid to a true surface in the center of the street, and also next to the curb if the curb cannot be used.

"Before SHAPING THE CUSHION a ½ in strip shall be laid on the curb, and guide timbers, or rail, and the template drawn over the same, after which the ½ in strip shall be removed, the cushion slightly moistened and rolled over its entire surface with a hand roller. The roller shall not be less than 36 in in diameter, 24 in in width, and shall weigh not less than 10 lb per in in width, and have a handle 12 ft in length. After rolling, the template shall be drawn over the curb and guide timbers or rail, to complete the cushion. The cushion shall be prepared at least 50 ft in advance of the brick laying.

"**Laying of the Brick.** The brick shall be laid in straight lines on edge, at right angles to the curb. At intersections, they shall be laid as directed. Brick shall be laid with the lug sides all in the same direction. Brick must be placed close together, both ends and sides, breaking joints at least 3 in. At every fourth course, the brick shall be driven together to secure tight joints and straight courses and all thick brick shall be removed. Brick shall be used with the best edge up. Broken, chipped or warped brick, not suitable to lay as a whole, may be used for batting. When any section shall contain more than 10% of culls, the brick shall be taken up and the cushion adjusted. Brick shall be laid from curb to curb, or car track to curb. No bats or broken brick shall be used except at curbs or at street-car tracks. Batting for closures shall immediately follow the laying. Joints shall be cut square with the top and sides of the brick. All joints must be kept clean and open to the bottom until filled as specified.

"**Street-Car Tracks.** Along the street-car tracks the brick must not be laid within ¼ in of the rail, and when rolled shall be ¼ in below the top of the rail. The space between the web of the rail and the brick shall be filled with cement mortar, consisting of 2 parts sand and 1 part Portland cement. The mortar shall be in proper condition and the edge constructed to a straight line before the brick are laid.

"**Expansion Joints for Cement Grout Filler.** Expansion joints shall be placed parallel with and at each of the curb lines, and shall be 1½ in in width. The joints shall be made by placing together on edge, parallel with the curb, two wedge-shaped strips 6 in in width, and dressed on two faces. The strip next to the curb shall be 1 in wide on top, beveled to a thickness of ½ in at the bottom, and the strip next to the brick shall be of the same dimensions and placed in a reverse position. The brick shall be laid lightly against said strips. Soon after the pavement has been grouted and the cement filler has set, and the pavement is in all other respects finished, the strips shall be removed, the joints thoroly cleaned out, and immediately completely filled with a bituminous filler composed of a material which, when penetrated by a No. 2 needle under a weight of 200 g for 1 min at a temperature of 0° C (32° F), will have a penetration of not less than 20, and when penetrated by a No. 2 needle under 50 g for 5 sec at a temperature of 46° C (115° F), will not have a penetration of over 100. A premolded expansion strip made of a material unaffected by the action of water or street liquids may be used along each curb line, if it meets all the requirements for the joint filler herein specified. These strips shall not be less than ¾ in in width for a 30 ft street or under, increasing proportionately to 1½ in in width for a 50-ft street or over.

"**Rolling.** After the brick in the pavement have been passed for rolling and the surface swept clean, the pavement shall be rolled with a roller weighing not less than 3 nor more than 5 tons, in the following manner: The brick next the curb shall be tamped with a hard wood tamper, to the proper grade. The rolling shall then commence near the curb at a very slow pace, and continue back and forth toward the center, until the center of the street is reached, then, passing to the opposite curb, it shall be repeated in the same manner to the center of the street. After this first passing of the roller the pace may be quickened and the rolling continued until the brick pavement has a smooth surface. The pavement shall then be rolled transversely at an angle of 45° from curb to curb, repeating the rolling in the opposite 45° direction. Before and after this transverse rolling has taken place, all broken or injured brick must be taken up and replaced with perfect ones. The substitute brick must be brought to the true surface by tamping. After final rolling the pavement shall be tested with a 10 ft straight-edge, laid parallel with the curb, and any depression exceeding ¼ in must be taken out. If necessary, the pavement shall be again rolled.

"**Portland Cement Grout Filler.** The filler shall be composed of 1 part each of fine, clean, sharp sand and Portland cement.

"The cement shall meet the requirements of the standard specifications for Portland cement of the Am. Soc. Test. Mat., adopted August 16, 1909, with subsequent amendments. The sand shall be clean and sharp, fairly well graded from that passing a 20-mesh sieve to that retained on a 100-mesh sieve. Sand shall be measured in a box having the same cubical contents as 1 sack of cement.

"Before any grouting is done, a sufficient amount of cement and an equal amount of sand to complete the work prepared for grouting at that time, but not to exceed 2 hours' run shall be thoroly mixed dry until the mass assumes a uniform color. From this mixture an amount not exceeding 2 cu ft shall be taken and placed in the grouting box and enough clean water added to obtain a grout that will penetrate to the bottom of the brick. From the time the water is applied until all is removed and floated into the joints of the pavement, the mixture must be kept in constant motion. A mechanical mixer approved by the Engineer that will meet these requirements may be used after the dry mixture of sand and cement has been made. Before the grout is applied the brick shall be thoroly wet by being gently sprayed. The water shall be added to this dry mixture in a box preferably about 4 ft 8 in long, 30 in wide, and 14 in deep, resting on legs of different lengths, so that the mixture will rapidly flow to the lower corner of the box, the bottom of which shall be about 3 in above the pavement. One box shall be used for each 14 ft in width of roadway, and at least two boxes must be used in all cases.

"The grout shall be removed from the box with scoop shovels and applied to the brick in front of the sweepers, who shall rapidly sweep it lengthwise of the brick into the unfilled joints, until the joints are filled to within not more than ½ in of the top of the brick. After the grout has had a chance to settle into the joint and before the initial set develops, the balance of every joint shall be filled with a thicker grout, and, if necessary, refilled, until the joints remain full to the top. After this application has had time to settle and before the initial set takes place, the pavement shall be finished to a smooth surface with a squeegee or wooden scraper having a rubber edge, which shall be worked over the brick at an angle with the brick.

"When completed and the cement has received its initial set, the pavement shall be covered with a ½ in layer of sand, which shall be frequently sprinkled in warm weather. No travel shall be permitted on the pavement for a period of at least 7 days after grouting, or longer, as the Engineer may require on account of weather conditions. Ample barricades and watchmen shall be provided by the contractor for the proper protection to the grouting.

"**Coal Tar Paving Pitch Filler.** The joints or spaces between the bricks, and those between the bricks and the curb, railroad tracks, around manholes, etc, shall be filled with coal tar paving pitch, which shall comply with the following requirements:

"Physical Properties. When in place in the pavement, it shall be of such character that it will adhere firmly to the paving brick and to the curb, and shall be sufficiently plastic to allow for the contraction and expansion in the pavement without developing cracks in the joints. The filler shall be such that it retain its consistency under extreme temperature. It shall be proof against action by water and all acids and alkalies to which the pavement may be exposed. The free carbon shall not be less than 25 nor more than 40%. The specific gravity shall not be less than 1.23 nor more than 1.30 at 15.5° C (60° F). It shall have a melting point varying not more than 8° from 57° C (5° from 135° F), determined by the cube method.

"Methods of Use. The filler shall be heated and poured into the joints to the full depth thereof, at a temperature of not less than 149° C (300° F), nor greater than 177° C (350° F). All joints shall be completely filled at the top. The top dressing of sand shall be spread over the pavement immediately after the filler is applied and while it is still soft. In cold weather the sand shall be heated so as to readily bond with the pitch. Extra care shall be used at the gutters and around catch basins, etc, to effectually prevent the leakage of water into the sub-roadway.

"**Asphalt Filler.** The interstices of the brick shall be completely filled with an asphalt filler heated to a temperature of not less than 177° C (350° F) nor more than 232° C (450° F). This asphalt filler shall not contain pitch nor any part of coal tar. It shall contain at least 98% of bitumen soluble in carbon bisulphide. It shall remain pliable at all temperatures to which it may be subjected as a street paving filler; it shall

be absolutely proof against water and street liquids; it shall firmly adhere to the brick and be pliable rather than rigid. The penetration shall conform to the following:

No. 2 needle, 5 sec, 100 g at 25° C (77° F), 25 to 60.
No. 2 needle, 1 min, 200 g at 0° C (32° F), not below 25.
No. 2 needle, 5 sec, 20 g at 46° C (115° F), not above 110.

Care shall be exercised to completely fill all openings around street structures and the street shall not be used for traffic until the filler is completely set. A top dressing of sand shall be spread immediately after the filler is applied and while it is still soft.

"Maintenance. The period of guaranty shall be 5 years. During the period of guaranty, whenever the surface of a vitrified brick pavement becomes uneven, holding water ¼ in or more in depth in a distance of 4 ft or less, or when the pavement has settled over trenches existing previous to the completion of the pavement, then the brick shall be taken up and relaid to proper crown and grade. Any brick which may be found soft, unsound, broken or disintegrated, and all portions of the pavement which may have become rough by reason of the chipping or breaking of the edges of the brick, so as to produce joints exceeding ½ in at a point ¼ in below the surface of the brick, shall be removed, and properly replaced with sound material.

"Note. All castings for manholes, catchbasins, etc, shall not be imbedded in the concrete foundation. They shall be made to rest on top of the foundation to allow the pavement to expand uniformly, thereby avoiding the cracking and crushing of the brick.

"Note to Engineer: Where medium or light traffic or other conditions exist, which, in the opinion of the Engineer, do not require a brick capable of giving an abrasive loss of only 22%, brick of a quality which will give a loss of 25 or even 28% may be used. While the committee is in favor of a cement grout filler, it believes that where conditions do not favor the use of the same, a bituminous filler may be used. For cement grout filler, the committee recommends a square edge brick."

Specifications for Brick Paving on Sand-Cement Mortar Bed, as adopted by the National Paving Brick Manufacturers' Assn. are, in part, as follows:

"Superfoundation. Upon that part of the foundation already prepared, there shall be added a superfoundation completing the whole, composed of 1 part of cement to 4 parts of sand, stone screenings or granulated slag, which, when thoroly rolled and compacted to a uniform density by means of a hand roller, shall be not more than 1 in in depth.

"Construction. The sand and cement for the added portion of the foundation shall be mixed in the proportions herein provided, by hand or mechanical mixer, until the mass attains a uniform shade and in such quantities that the operations of constructing the superfoundation may proceed continuously. The superfoundation shall be shaped to a true surface parallel with the surface of the finished roadway, by means of a template extending the entire width of the roadway, drawn forward upon the curbs or guide rails. When the width of the roadway precludes the use of a template spanning the entire distance the operations of shaping the superfoundation shall be performed upon sections thereof, using scantling laid upon the foundation as the guide rails. After the superfoundation has been spread and struck off a depth not less than ¼ in above the finished depth herein provided, it shall be thoroly and uniformly compacted by rolling. The roller used for this purpose shall be of the hand type, weighing not more than 10 lb per in of length. It shall be not more than 24 in in diameter, nor more than 30 in in length. Rolling shall commence at the curb and continue parallel to it at a slow pace, moving backward and forward until the opposite curb is reached. Any depressions created by rolling shall be lightly roughened by means of rakes and a sufficient quantity of aggregate mixture be added, so that when again struck off and rolled the surface shall conform to that herein provided. The operations of striking off and rolling shall be repeated until the entire superfoundation is uniformly dense and free from depressions. When the use of the template and guide rails for striking off any portion of the superfoundation is impracticable, it shall be shaped to the surface required by hand luting. All provisions for rolling, compacting and smoothing shall be observed.

"Laying the Brick. Upon the superfoundation as prepared, the brick shall be immediately laid with the better edge uppermost and the projections in one direction. Only whole brick shall be used except as provided or by special direction of the engineer."

Specifications for Brick Paving on a Green Concrete Foundation, as

adopted by the National Paving Brick Manufacturers' Assn. are, in part, as follows:

"The Subgrade, if dry, shall be lightly sprinkled with water before placing the concrete.

"Concrete for the Foundation shall be deposited, struck off and finished to the depth of ....inches as provided in the plans and specifications so that when complete, the surface shall be parallel to, and........inches below the grade of the finished roadway. The surface shall be smooth and uniformly finished, with the coarse aggregate thoroly embedded in mortar. Concrete in place shall have been so mixed, deposited, and finished, that the coarse and fine aggregate shall be uniformly distributed thruout the mass. The concrete shall be brought to the required surface smoothness and condition for laying the brick thereon by adding thereto a thin coating of sand and cement.

"The Sand and Cement for the Thin Coating shall be of a quality equal to that used in the fine aggregate in the concrete. They shall be thoroly mixed dry in advance in a mechanical batch mixer, in the proportion of 1 part cement to 3 parts of sand by volume. Mixing shall continue until the mass attains a uniform shade. Sufficient quantity shall be prepared at intervals in order that there shall be no interruption in preparing the surface of the concrete for brick laying.

"Steel Forms shall be utilized to retain the concrete and brick and serve as guide rails for the template, and when so used, shall be true to line and grade.

"Double Template. The concrete shall be brought within the requirements by means of a double template which shall consist of a 6-in steel I-beam in front and a 6-in steel channel or I-beam to the rear, held in a rigid frame with the two members parallel, spaced 2 ft from center to center, and shaped to conform to the cross-section of the roadway. The rear member shall be held in the frame with the bottom $^3/_{16}$ in higher than that of the frame member. Rollers shall be attached to the frame which shall rest, when in use, upon the guide rails.

"In Shaping the Concrete deposited from the mixer, it shall be thoroly spaded, settled and roughly surfaced immediately ahead of the double template. A sufficient amount of dry mixture for the thin coating shall be supplied continually between the framed templates so that in the forward movement, the rear template shall distribute the necessary film over the entire surface, producing the required smoothness. In cases where the use of the double-framed template is impracticable, the required surface shall be secured by templates or by hand luting.

"Note: By reason of the fact that the rear cutting edge of the double template is $^3/_{16}$ in higher than the front cutting edge, the forward movement of the template as described performs two operations simultaneously, namely: That of striking off the concrete which has been deposited upon the subgrade and spreading over its surface the $^3/_{16}$ in film of the dry mixture, which being of equal quality of the mortar in the concrete becomes an integral part of the concrete. Concrete of a consistency which will sustain the brick surface uniformly during the laying, rolling, and filling the joints is a necessary prerequisite. It is equally necessary, too, that the green concrete shall be of a consistency affording a mortar surface which will insure a perfect adhesion of the brick. The use of transverse joints in the surface or base of the roadway should not be permitted.

"Conditions Governing Laying Concrete. The use of partially hardened mortar or concrete, remixed with water, is prohibited. No concrete shall be mixed or deposited when the air temperature is below 0° C (32° F), unless during the mixing the aggregates shall be heated so that when placed, the temperature of the concrete shall be not less than 15°C (60° F). The pavement shall then be protected by sufficient covering against freezing. In no event shall concrete be deposited upon a frozen subgrade.

"Laying the Brick. Upon the foundation as prepared, the brick shall be immediately laid with the better edge uppermost and the projections in one direction. Only whole brick shall be used except as provided or by special direction of the engineer."

16. Construction Cost Data

The price of brick pavements, including foundations, varies according to local conditions, but generally will range between $1.25 and $2.50 per sq yd,

under contracts which include a fair profit to the contractor. These figures may be subdivided into items as follows:

	Minimum Cost per Sq Yd	Maximum Cost per Sq Yd
Preparation of subgrade after excavation or embankment is completed	$0.02	$0.05
Artificial foundation	0.35	
Concrete foundation, 6 in		
Materials		0.80
Mixing and placing		0.10
Sand cushion		
Materials	0.10	0.20
Placing, compacting and trimming	0.015	0.03
Brick wearing course		
Brick, hauling and piling	0.65	1.10
Laying	0.06	0.10
Rolling	0.02	0.05
Grouting	0.025	0.05
Expansion joints	0.01	0.02
	$1.25	$2.50

The necessary cleaning up of the work, sprinkling and otherwise keeping moist of the grout filler after placing, and other work incidental to the performance of the contract under such specifications as those of the National Paving Brick Manufacturers' Assn., are covered by these figures as well as interest, rental, or other charges for machinery or tools and a profit to the contractor. See (6), (7), (23), (30c) and (55).

A Formula (53) for estimating the cost of brick pavements in rural districts is as follows: Cost per square yard of foundation of 6 in of cement-concrete equals $1.90L + 0.213C + 0.138S + 0.157A + 0.040B$, where C equals the cost of cement per barrel; S equals the cost of sand per cubic yard; A equals the cost of the aggregate per cubic yard; B equals the cost of brick per thousand; and L equals the cost of labor per hour.

"Gary, Ind. (23). Contract prices for brick pavements on 6-in concrete base varied during 1914 from $2.13 to $2.18 per sq yd, while the cost data compiled from inspectors' reports show a cost to the contractor of from $1.62 to $1.72. This cost price does not include overhead expense of any kind, nor does it include the discount item referred to above. Grading is paid for as a separate item, as is all other incidental work, such as curbs, sidewalks, catch-basins, headers, etc.

Table VI.—Cost of Brick Pavement in Gary, Ind., in 1914

Improvement		Madison Ave		26th Ave		25th Ave	
Sq Yd Pavement		5289.8		8522.4		8727.1	
Labor Item	Rate in Cents	Hr	Per Sq Yd	Hr	Per Sq Yd	Hr	Per Sq Yd
Team	60	143	......	130	......	278	......
Labor	20 to 30	1746	......	1673	......	2612	......

*Includes cost of making sand cushion, laying, rolling and grouting brick."

Method of Figuring Cost of Brick Paving on a Green Concrete Foundation (26). "This is a method of arriving at a COST only. The figures used may not apply at all to any case in hand, but in arriving at what the cost of a brick road is in any particular case the actual cost of the several items must be ascertained. Then the real cost can be determined by following the method outlined."

Assumed prices for illustration: Cement at $1.40 per bbl delivered. 4 in brick at $14 per M, f. o. b. factory. Sand at $1 per ton delivered, at 3000 lb per cu yd. Broken stone, $1.25 per ton delivered, at 2600 lb per cu yd. Haul for brick, 1½ miles at 30 cents per ton-mile.

Assumed proportions: Base, 4 in, 1 : 3 : 6 concrete, requiring per cu yd 1 bbl cement, 0.45 cu yd sand and 0.95 cu yd stone.

Cost of Concrete Base:	Per Cu Yd	Per Sq Yd
Cement	$1.400	
Sand $3000 \times \frac{0.45}{2000} \times \$1.00 =$	0.675	
Stone $2600 \times \frac{0.95}{2000} \times \$1.25 =$	1.544	
Water	0.100	
Mixing, placing and finishing	0.650	
	9)$4.369(	$0.485

Cost of Brick:	Per Ton	Per Sq Yd	
Brick f. o. b. factory at $14.00 per M	$2.80	$0.560	
Freight	0.60	0.120	
Hauling, 1½ mile at 30 cents	0.45	0.090	
Laying and rolling		0.080	
			$0.850

Cost of Grouting:

Cement grout filler, 1 bbl cement + 1 bbl sand grouts, 25 sq yd, 4 in brick.

	25 Sq Yd		
1 bbl cement	$1.400		
1 bbl sand	0.222		
	25)$1.622(	$0.065	
Mixing and applying:		0.040	
			0.105
Covering and Curing:			0.005
Total			$1.445

17. Special Forms of Brick Paving

Hillside Brick. The special form known as hillside brick has recently come on the market in response to a demand for reduced slipperiness in brick pavements on grades. The hillside brick is the ordinary paving brick with one of the longest edges in the face exposed to traffic chamfered off or with grooves in its wearing face.

The Chamfered Brick are laid as usual except that care is taken to have this chamfered edge always placed down grade, and next to the square edge of the brick adjacent. After the joints have been filled with cement grout in the ordinary manner, the joint filler, just before it is set hard, is removed from the chamfered space by means of stiff brooms, and a fairly deep groove is thus left across the pavement on the up-hill side of each course. The ridged or corrugated pavement thus presented to the traffic is less slippery than the ordinary smooth pavement with completely filled cement joints.

Table VII.—Character and Cost of Brick Pavements Laid in 1916 in Several Cities

From *Municipal Engineering*, March, 1917

	Sq Yd	Base: Thickness in In	Base: Proportions	Cushion: Thickness in In	Cushion: Kind	Thickness of Brick in In			Cost per Sq Yd Pavement and Foundation

Grooved Brick. A novel type of hillside brick was laid in Toronto in 1914. It is described (22a) as "combining the distinctive features of the ordinary wire-cut-lug brick with two transverse grooves, about 3 in apart, on the wearing surface, designed to give horses a foothold on steep grades. The bricks are laid longitudinally with the street. Joints are broken on each brick so that instead of extending in lines across the entire width of the street, as in the case with ordinary hillside brick, each groove is no longer than the width of the brick. This affords shoe-calks opportunity to get a grip almost anywhere. However, as the grooves are broken at short intervals, broad tires bridge them on alternate courses of brick and roll over the pavement without experiencing an appreciable jolt.

"None of the hillside brick was laid in courses at right angles to the curb, but they were laid obliquely across the street, a method necessitated by laying the brick longitudinally in the direction of the length of the street. The pavement has a 6-in concrete foundation and a 1½-in sand bed, with cement-grout filler mixed 1 to 1. Grouting was begun at the foot of the grade, as otherwise the thin grout would have flowed down the longitudinal joints and overflowed the lower part of the pavement. Small quantities of grout by the shovelful were poured at a time, and the surplus was quickly brushed forward up the grade. The final course of grout was squeegeed until the surface of the joints was full, flush with the pavement, care being taken to keep the joints full until t e setting began. After the final course of filler began to set, the transverse grooves in the brick were brushed out with wire brooms. The brushing was not really necessary, as the grout in the grooves wears out under the impact of horses' shoe-calks, but the process made the grooves serviceable at once." See also (31b).

Nose Brick are brick of a special form for fitting against the heads of street-car rails. They are like ordinary paving brick except that at one end the corner of the upper side is rounded off into an ogee curve, so as to permit the end of the brick to go up against the web of the rail and the surface of the brick to be close to the head of the rail near the top, thus enabling a tighter joint to be made between the paving and the rail. This result is similarly attained by the use of special filler brick, made with chamfered edges, of the proper thickness to permit the brick to be placed in the area between the web of the rail and the plane of the outside of the head, so that the ordinary brick may then abut against the head of the rail and the outside face of the filler brick. On the inside of the T-rail, where a flange-way must be provided for the street-car wheels, filler brick are provided for occupying the area between the web and the plane on the inside of the head of the rail, and then a special form of brick similar to hillside brick, and having one chamfered edge, are laid lengthwise as runners next to the filler brick. A channel for the street-car flanges is thus provided, the inner side of which is sloping instead of vertical, enabling narrow tired vehicles to avoid being held by this channel. The proper construction of a brick pavement in connection with street-car tracks is an extremely important and difficult matter. The area of greatest weakness in brick pavements is usually a narrow one along the street-car rails, and this weakness appears to be occasioned by the usual difference in rigidity between the street-railway construction and that of the brick pavement, together with a usual lack of precaution against the entrance of water at this point to the interior of the pavement construction, or the difficulty of maintaining the proper degree of imperviousness in the pavement within this area. Any entrance of water along the rail will sooner or later affect the position of the sand cushion under the pavement or even the foundations and then the pavement itself. The filling of the irregular area between the web of the rail and the vertical planes passing thru the outsides of the head of the rail is a most difficult matter, and various expedients have been tried.

Filling this area with mortar or concrete is usually most difficult if not impracticable. The filler brick above mentioned seem to be an improvement, but their rigidity, and that of the mortar used with them, frequently results in the cracking of this filler where the rail is not sufficiently rigid under the loads coming on it, and such cracking permits the entrance of moisture or the escape of the sand cushion. In Baltimore, it has been the practice to use wooden plank of the proper thickness to fill these spaces, but it is difficult to secure tight joints in the plank around the fish plates, tie rods, bonds, etc. The usual concentration of the effects of traffic, on the strip of the pavement immediately adjacent to the rail, demands the greatest possible precautions and the best possible work on this portion of the pavement if uniformity of the pavement surface is to be had in service. See Sect. 23. Vitrified brick or other blocks are frequently used in one or two lines as runners along the rails of street-car tracks where a bituminous pavement is used for the balance of the roadway, because of the difficulties of constructing and maintaining a proper continuity in the bituminous pavement if brought against the head of the rail. Where the car track construction is of a high character, the use of brick or similar smooth blocks gives satisfaction, but if the car track construction is what might be called flimsy and unsubstantial or lacks rigidity under the vehicles using it, the relatively small mass of the brick does not seem to be sufficient to permit it to give the satisfactory results desired. In such cases, the brick even become displaced, the joints open and water is permitted to enter the pavement at this joint. This results in more rapid deterioration of the roadway surface as a whole. In such cases of inferior construction of car tracks in the pavement, the use of brick or similar small smooth blocks should be avoided, and larger blocks, such as stone paving blocks, should be used instead, in order to secure the utmost advantage to be had from their greater inertia and ability to resist displacement.

Bituminized Brick were laid on Stark Street, Portland, Oregon, in 1893. The brick had been boiled in coal tar before being laid, and this section of pavement remained in service for 17 years. In 1906, nose brick, which had been boiled in asphalt, were laid along the street-railway tracks in Los Angeles, and in 1912, a small area, at the corner of Second and Market Streets, San Francisco, was laid with similar material. Adjoining this latter area, sections of basalt block and sheet-asphalt were laid. It is claimed that the treated brick showed less wear after 2 years' use than either of the other sections. Similar pavements of brick soaked or boiled in bituminous material, have been laid in Nashville and Chattanooga, Tenn. The treatment of the brick in the above cases was more or less crude and caused the bituminous material to penetrate only from ½ to ¾ in below the surface. The recently developed treatment causes a much more thoro impregnation of the brick and saturates the brick with from 6% to 15% of its weight with bitumen. The treatment seems to increase the imperviousness of the brick, improve the adhesion of any bituminous filler used in the joints, reduce the noisiness and slipperiness of the pavement, and increase the sanitariness of the pavement. More important, however, than any of these facts is apparently the effect on the wearing qualities of the brick. A remarkable reduction in the loss under the rattler test is apparently secured. Perhaps the most noticeable result is the tremendous increase in uniformity of loss among the individual brick when they have been properly bituminized. Table VIII shows the results of some tests made by R. W. Hunt & Co., on brick both treated and untreated. In

Table VIII.—Comparative Tests of Shale and Clay Brick, Treated and Untreated with Bituminous Material

Brick	Made From	Weight Before Test in Lb		Weight After Test in Lb		Percent Loss in Weight	
		Before Treatment	After Treatment	Before Treatment	After Treatment	Before Treatment	After Treatment
Sterling Brick Co.	Shale	50.66	56.75	23.64	48.37	58.34	14.77
Terre Haute.........	Shale	46.50	48.97	17.69	42.75	61.96	12.70
Mack Manufacturing Co.	Fire Clay and Shale	45.25	47.49	31.32	40.98	30.79	13.71
Corning Block........	Shale	48.65	51.33	36.77	44.50	24.42	13.31
Jamestown Shale Paving Co.	Shale	49.75	54.60	30.18	47.24	39.34	13.48
Hocking Valley Brick Co.	Shale	47.95	49.94	34.32	43.48	28.43	12.94
Metropolitan Block....	Shale	50.03	54.53	38.25	48.28	23.55	11.46

Note: In each case ten bricks were used, 5 treated and 5 untreated. Weight of abrasive material as follows: Small shot, 225 lb; large shot, 75 lb. Number of revolutions, 1800 at rate of 30 rev per min. Each brick weighed separately before and after test.

each case, bricks of the same quality and from the same batch were used in the comparative tests and were in all cases seconds. It will be seen that while the rattler loss of the untreated brick runs from 23 to over 60%, that of the treated brick runs between 11.4 and 14.8%. The uniformity of the brick under wear (see Art. 8) seems therefore tremendously increased. Further, the tests apparently show that a brick which has not been burned to the ordinary degree of vitrification can be made, by this treatment, to give an abrasion loss lower than ordinarily specified for the best grade of vitrified brick. Apparently the impregnating bitumen by its adhesiveness prevents the brick from losing particles which would break off the untreated brick, and thus perhaps cushions the cell walls of the brick so as to greatly increase their resistance against breaking down under shock. From the manufacturers' point of view, the treatment will apparently enable the burning of the brick to be stopped at a considerably lower point than is now necessary for the No. 1 pavers, and further enable the disposing of practically all of each burning as No. 1 pavers, instead of only from 60 to 70% as is usually the case. Apparently a great improvement of even the best vitrified brick pavement is offered by bituminizing brick. If, after more thoro trial, the pavement shall fulfill the promise held out by the experience to date, a wider field will be opened for such pavement and many of the now existing objections to vitrified brick pavements will be removed.

The Manufacture of Bituminized Brick is described as follows: The burning as ordinarily conducted is stopped 2 or 3 days sooner than for vitrified pavers. The brick are then cooled down to a handling temperature and run into a tight cylinder. A vacuum of 25 in is produced in the cylinder while the brick are at a temperature of approximately 177° C (350° F). The bituminous material, in the meantime having been heated in a tank, is now discharged into the cylinder, filling it to a point above the brick, where a pressure of approximately 160 lb per sq in is produced and maintained from 1 to 3 hr. The cylinder is then drained, all surplus bituminous material being returned to the tank. The brick are then transferred to an annealing chamber and allowed to cool. It is claimed that the process produces a uniform impregnation.

Vitrified Cubes. In the effort to reduce the first cost of vitrified brick pavements, J. Y. McClintock, County Engineer of Monroe County, N. Y., in 1908 began experimenting in the use of artificial cubes made from local clays and shales in the same manner as the ordinary vitrified paving brick. These cubes were 2 or 2½ in each way, and were laid on various kinds of foundations with a sand cushion under the cubes. Experiments with cubes of other materials were made contemporaneously. The vitrified clay and shale cubes in these experiments have been remarkably successful under the local traffic conditions. The joint filler used was in some cases sand or sandy loam; in some, cement grout; and in other cases, bituminous cement was used. The cubes were laid in different ways, in some cases, individually by hand; in some cases, from pallets containing from 124 to 144 cubes each; and in other cases, they were simply loosely spread and raked into place. It was found that too great a variation in the depth of the sand cushion was as undesirable as in the case of vitrified brick. Too wide joints permitted the removal of a sandy filler by fast moving automobile traffic, resulting in excessive spalling and wear along the joint lines. In the latter case, improvement was had by the use of a bituminous material over the pavement after the surface had been cleaned off and the sandy material in the joints removed to a moderate, but uniform, depth below the surface of the cubes. It was further found that the edge of the cube pavement could be successfully held by a macadam shoulder, thus enabling a gradual transition from the hard surface of the road to the earth shoulder outside, and the prevention of ruts along the edges of the harder pavement. The cube pavement seems to be sufficiently flexible under frost action to make it well suited for a surfacing with a macadam base, and to give a surface that is very satisfactory in both wet and dry weather for traffic. Furthermore, as it can be laid early and late in the working season and easily patched, it seems to have important advantages. The resistance to wear of these vitrified cube pavements has been admirable, and when laid on a concrete foundation and with grouted joints, they have worn very well under heavy motor traffic and medium team traffic. When laid on a macadam base with fairly wide sand joints, they stand well under moderate traffic. When so laid with a sand filler and superficially coated with bituminous material, they have stood considerably heavier traffic. The indications are that a well burned vitrified shale cube laid on a concrete foundation with cement grouted joints will stand satisfactorily the traffic on all but a few of the most heavily travelled country roads.

The cost of the first vitrified cube pavements on an old macadam base was reported in 1909 as $1.17 per sq yd. The cost at the plant was $3.20 per thousand for the cubes, or 71 cents per sq yd, while it is estimated that it would be possible to reduce this cost 50% by more efficient methods in burning and handling the cubes. In 1913, an actual reduction in the cost of the cubes to $2.50 per thousand or 55 cents per sq yd, was accomplished. The freight on the cubes from the plant was 11 cents per sq yd, or the cost delivered was 66 cents per sq yd, as against 85 to 90 cents per sq yd for ordinary paving brick. See (37).

MAINTENANCE

18. Methods of Maintenance

The maintenance of a properly built brick pavement should be so slight as hardly to justify extended discussion of the subject. By maintenance is to be understood no consideration of the cleaning of the surface. This

cleaning, while as important in the case of brick pavements as in any others, is a separate subject and fully discussed under its proper head (see Sect. 22). The maintenance proper of a brick pavement will consist of restoring the uniformity of its surface or correcting defects resulting from faults in the construction. From one cause or another, an individual brick in the surface may prove to be or become defective and immediately defects in the surrounding area appear and grow rapidly. The removal of the defective brick or bricks and their replacement by suitable bricks with a concentrated view to securing the greatest possible homogeneity and uniformity of the entire surface should be had as promptly as possible.

The Expansion Joints may need some attention in order that the elastic material in them shall remain everywhere even with and protecting the edges of the bricks adjoining the joint. Also, in case cracks appear in the pavement, these opportunities for water to reach the interior, with probable resultant damage, should be promptly and finally closed by filling them with melted bituminous cement of proper character.

The Wearing Down of the Surface of a well built vitrified brick pavement is such a slow matter that its end of life on this line is beyond contemplation. The disintegration of individual bricks in the pavement is another matter and not by any means infrequent. The deterioration of considerable areas with a resulting damage, even to the point of a just condemnation of the whole pavement, is rapid if neglect is accorded the first symptoms of such a process taking place.

Bituminous-Filled Brick Pavements have sometimes given excellent service with slight maintenance expenditures for many years until they have become objectionable, under the local conditions, for the reason of their then excessive noisiness due to the badly worn-off upper edges of the brick. Some such pavements have then been taken up and the same brick relaid bottom up with satisfactory results. This might be considered Maintenance. It would be impracticable in cases where cement grout has been originally used for the joint filler.

Replacing Brick Paving After Refilling Excavations (45). "In making the cut thru the pavement, alternate bricks will sometimes be broken in the middle, leaving a series of broken bricks along the edge of the cut. These half bricks must be toothed out with a chisel so that none but whole bricks remain. It is then possible to break joints in patching. A patch which does not dove-tail into the original pavement, but leaves a long straight longitudinal joint between patch and pavement, cannot be too strongly condemned. A long handled 18-in chisel is the best instrument to use in making the original cut in a pavement. After an opening has been broken with a maul, the chisel can be used to cut and pry out each brick separately, making a cleaner opening and facilitating the patcher's job. Matching brick for the patch is an important matter. If the color and size coincide with the original pavement, the patch will be scarcely noticeable. The brick should be carefully measured in matching for size. Where the new brick are a hairbreadth thicker than the old ones, the courses are thrown out of series and good joints are impossible."

Removing and Cleaning Brick by Compressed Air Power (25). "The equipment used for this work consisted of a 15-HP Sullivan Class W-K-3, portable, single stage air compressor, the compressor being operated by a gasoline engine, mounted on the same truck with the compressor and operating the compressor thru a gear and pinion. This outfit furnished compressed air for a Sullivan DA-15, 25 lb plug drill, and a Sullivan DB-13 hand bushing tool equipped with bits like that on a cold chisel. The larger of the two tools is used for tearing up the brick, and the smaller for cleaning the old mortar and grout from them. With the plug drill one man can remove 4 sq ft of pavement in 15 or 20 min, taking the bricks up either one brick at a time or several, as desired. When doing this work by hand, the workmen were frequently obliged to break several bricks which were perfectly good, in order to get out one,

so that the loss was considerable. Before the purchase of this outfit the cost of removing and cleaning bricks by hand was $24 per M and a crew of 10 men was able to handle 1000 bricks per day. The detailed cost of operating the compressor and drill outfit was as follows:

1 Compressor engineer	$3.00
7 Gal of gas at 18 cents	1.26
4 Operators at $1.85	7.40
Lubricating oil	0.25
Total cost per day	$11.91

"The above does not include interest or depreciation. Crowley estimates that about 2000 bricks are removed and cleaned in 8 hr with the two tools. This brings the cost of taking up and cleaning to $5.96 per M bricks. On work done with this outfit in 1914 a crew of 40 men was cut down to 18 men. It is estimated that this outfit pays for itself on every 100 000 bricks taken up and cleaned. Savings included labor on the brick, saving in the sand cushion, saving in time in making the bed under the brick and in laying the brick. Cement and grouting are also saved."

19. Bituminous Carpets

The effort has been made to reduce the noise and slipperiness of some brick pavements as well as to lengthen their life under traffic by applying to their surfaces a carpet composed of bituminous cement and sand or gravel. Some of these experiments have been fairly successful while others have been quite the opposite. The obstacles to success seem to be mainly those of securing proper adhesion of the carpet to the brick surface and of securing such a proper body to, or cohesion in, the carpet itself, as will enable it to resist successfully the tendencies of the traffic to strip the carpet from the pavement or to disintegrate it. If the carpet is to be successful, it must be able to resist to the last the tendency to peel off the brick surface, and it must have sufficient body to resist the disintegrating effect of the traffic which tends to push it into waves, or to crumble it into a loose mass. It is evident from the experiments that have been made that there is a limit to the amount of traffic which any such carpet can successfully withstand, and the attempt to provide a bituminous carpet on a brick pavement, should not be made where the severity of the traffic is greater than a certain degree. At the present time, it is impossible to express this limited degree of severity of traffic in formulas or figures. Aside from the adhesive and cohesive qualities of the bituminous cement itself, the composition of the carpet and its thickness have much to do with its resistance to disintegration under traffic. For instance, considering that a sheet-asphalt pavement is a carpet, there is no reason why it could not be laid on a brick pavement as a foundation, and its ability to withstand traffic when so laid would be equal to the ordinary ability in this direction of any sheet-asphalt pavement properly proportioned and properly laid. On the other hand, it is evident that a very thin carpet composed of the same asphaltic cement and sand would be least resistant under the same traffic. Between these two extremes may be expected to be found various mixtures and thicknesses suitable for different degrees of traffic. The adherence of carpets to brick pavements seems to be more satisfactory in cases where they are placed on pavements with bituminous joints than in those cases where a cement filler has been used in the joints. It would probably be greatest on bituminized brick (see Art. 17). See (28).

SECTION 21

CEMENT-CONCRETE PAVEMENTS

BY

WALTER WILSON CROSBY

CONSULTING ENGINEER, BALTIMORE, MARYLAND

GENERAL DATA

1. Historical Development

In 1879 North (51) stated that "In Scotland a concrete has been used with Portland cement, for binding. The surface was very good, but when the road commenced to break, it went to pieces very fast."

The First Portland Cement-Concrete Pavements in the United States are usually referred to as being laid in Bellefontaine, Ohio, in 1894, but as a matter of fact, the year before, J. Y. McClintock, County Engineer of Monroe County, N. Y., put down on South Fitzhugh St., Rochester, a section of Portland cement grouted macadam. This was a forerunner of the modern concrete pavement of the Hassam type. An excerpt from McClintock's 1894 Report (55) is as follows:

"There are many miles of streets where a cheap pavement is requisite and where macadam with trap rock would be suitable except that it seems desirable to get rid

of the small amount of mud which is usually present, and to have a surface that can be washed off clean. To meet this requirement we tried in 1893 the following on South Fitzhugh St. north of the canal. The surface of an existing macadam pavement was picked off and a layer of trap rock 6 in thick in the middle and 2 in thick at edge of paved gutters was put on and thoroly rolled with a steam roller. After this was done, instead of putting on a binding material and rolling that in as usual, Portland cement grout, one of sand to one of cement, mixed to the consistency of cream was carefully poured in so as to fill all the voids between the broken stone and form a solid matrix to hold each stone firmly in position. The stone was thoroly wet just before pouring in the grout. One barrel of cement was used to each 8.7 sq yd of pavement. After the mortar had set for 24 hr, sand was thrown over the surface and water was sprinkled upon it and all travel was kept off it for 9 days. This has been down 8 months and already shows that the size of stone used was too small; it would all pass thru a 1½ in ring. The stones are so small that the calk of a horse shoe throws a stone out bodily sometimes. It will be well to try this again with stones which will pass a 3 in ring and will not pass a 2 in ring. The cost of this pavement was $1 per sq yd."

McClintock in March, 1913, testified concerning this work, in the case of the Hassam Paving Co. versus the Consolidated Contract Co., as follows: "The piece of pavement laid developed irregular temperature cracks and on one portion of it where the hacks stood in the shade of the court house, the horses would drill holes with their feet in kicking off flies, so that it soon became a question of how the pavement could be maintained. (After eight months' use, the horses' calks were picking out some of the individual stones.) It was some 2½ years after the pavement was laid, . . . that it was deemed wise by the city authorities to cover the new portion of the roadway with asphalt.

The Bellefontaine Pavements were of the two course mixed type. From 1894 until 1909, the construction of concrete pavements of either type made little headway, one reason probably being the high first cost of such pavements under the then existing conditions, and another being the especial difficulty of making minor repairs to them.

Wayne County, Mich., began in 1909 the construction of a considerable mileage of concrete pavements. While this work was at first largely of an experimental nature, it was intelligently done, and the wide advertisement of the success of the results induced further experiments in many localities.

Table 1.—Summary of Square Yards of Concrete Pavements on Roads, Streets, and Alleys Constructed to December 1, 1916 (53b)

2. Characteristics

For the sake of making clear the statements to follow, let it be assumed primarily that a cement-concrete pavement is one in which the artificial surfacing for the roadway is built of a concrete composed of hydraulic cement, sand, and gravel or broken stone, all of predetermined proportions, and is not covered, or protected from wear, by a carpet or coating of appreciable thickness of bituminous cement and other material. Then all those roadways, of which a cement-concrete layer is covered by a carpet of bituminous material, will naturally fall together into another class where a concrete base or foundation supports a wearing surface composed of block paving, sheet or rock asphalt, bituminous carpets, etc, and in the consideration of these instances of the use of concrete, the latter will be referred to as the concrete foundation.

The use of concrete for both roadway surfaces and foundations is not new. In 1893 the concrete pavement was discovered, tried out and abandoned. It was found to possess certain inherent defects and, under the then existing conditions, these proved so serious that its economical use was found to be limited so as to result in the practical abandonment of this form of surfacing for the time being. With the changed conditions now existing, the use of concrete for roadways has again begun. The increase of traffic has demanded stronger roads. The reduced ratio of horse-drawn to total traffic has changed the average character of the stresses on the surfacing material. The immense reduction in the cost of hydraulic cement and the improvements in machinery for mixing and placing the concrete have aided the latter to compete with other road crusts in first cost and also in long-run cost. It seems that under the changed conditions there are at present many cases where existing circumstances, such, for instance, as poor natural foundation for, and heavy traffic on the road, or convenience in the supply of materials for concrete, justify or even demand its selection for at least a part of the road crust. On the other hand, the tendency of certain road authorities and others to rush to concrete as a panacea for all road ills is to be deplored as both irrational and extravagant. In these days the great problem for road authorities is the proper selection of the form of construction best suited for the circumstances of any particular case, and a sufficient variety of surfacings, including concrete, is now available to permit true economy to be had by a proper choice.

Of the factors influencing the decision for or against the selection of concrete as the road surfacing may be considered first cost, long-run cost, durability, ease of maintenance, cleanliness, resistance to traction, slipperiness, sanitariness, acceptability, and favorableness to travel.

Cost. Only too frequently, this consideration is limited to first cost and fails to include, as it should, the interest charges on first cost and the cost of maintaining the pavement in as good condition as when first completed, or a depreciation charge, in order that a fair comparison may be drawn. See (15). Concrete can never be as low in first-cost as macadam under the same conditions, because of the introduction into the former of cement for which an additional cost has to be met. Ordinarily competition may be had, often successfully, by a proper assumption that a less thickness of concrete will be as strong as the macadam to be prescribed, and further, that it is frequently possible to use in the concrete a local material for the aggregate which may be secured at a smaller cost, than necessary for a proper stone for the macadam. A local granite may make an excellent

concrete, when it would prove entirely unsatisfactory, because of its lack of binding qualities, for macadam, and, if macadam were to be built, the cost of importing a suitable stone might offset the additional cost of making concrete from the local granite. In the same way, where small sandy gravel is plentiful in a locality and good stone for broken stone macadam is required to be imported at a considerable expense, frequently gravel concrete roads or gravel concrete foundations, carrying a bituminous surface, will be found to be the economical solution. Contrary to the arguments of many of the advocates of concrete pavements, a concrete surfacing is not permanent in the sense that it will last indefinitely without repair. Concrete roadways, in addition to the interest charges to be figured in their long run cost, require continuous expense for maintenance and repair. Except possibly in those cases where a curb adjoins the edges of the concrete roadway, the shoulders, even if the concrete itself does not, begin the day after the completion of the roadway to need maintenance. While the shoulder maintenance may not be a part of the maintenance charges for the concrete itself, it certainly is a part of the road maintenance especially where, in order to keep the first cost down, the concrete surface has been built too narrow in width to carry on it all the traffic and a considerable portion of the latter constantly turns out on the shoulders. The concrete surfacing itself will, after a period dependent of course on local conditions, require repairs and it is an inherent difficulty of concrete, that repairs to it are not easily made. This fact was one of the main reasons for the abandonment of the earlier efforts to use concrete for roadway surfaces. While these repairs may seem in some respects relatively slight, the expense for them will be inversely large. Reliable figures of cost for maintenance of concrete roadways are not as yet at hand but the foregoing may serve to indicate, from the point of view of cost, the factors to be considered in this connection and the points of weakness in some of the arguments that have been advanced for the more general adoption of concrete roadway surfaces.

Durability. Reference has been made to the fact that concrete is not easy to repair. The frequency of repair may depend largely on local conditions, but it is also affected by certain peculiarities of any concrete. The mixing together of four different materials and the placing of the resulting mass in the roadway give many opportunities for irregularities to occur. A most desirable feature of any road surface is an ability to wear uniformly and this is frequently, if not generally, more desirable than a less uniform, even if slower, rate of wear. The difficulties in the way of the necessarily high degree of uniformity in cement-concrete for roadway surfaces are apparent, when it is recognized that few sources of broken stone deliver a uniform product; that there is frequently considerable variation in the ledge or quarry itself; that there often is variation even between the products of different days from the crusher and screens; and that segregation of the smaller from the larger sizes generally occurs in loading, shipping and handling this product. The same may be said as regards the sand in many cases. The quantity of water present in the mixture is frequently more or less irregular, and segregation and other causes for non-uniformity generally arise during the mixing and placing of the concrete. All these contribute to the presence so generally noted in concrete roadway surfaces of spots of unequal abilities to resist wear and to the consequently resulting holes so difficult of proper repair, which form one of the main objections to this type of pavement. While proper supervision does reduce to some extent the lack of homegeneity in results, certain inherent irregularities can be

only reduced by improved mechanical means while certain others seem inevitable. For instance, the natural irregularity in position of the stone in the surface of the placed concrete may be reduced to a considerable extent by rolling so that, just as in good broken-stone macadam, the majority of the larger pieces of stone in the surface will lie with a face exposed to subsequent wear instead of an edge as is found in most cases of insufficiently rolled macadam. Harrowing a layer of broken stone will result in greater uniformity as to size of the pieces of stone in the surface. Hence there seems to be good ground for some of the claims of the advocates of a concrete roadway surface formed by grouting the broken stone spread and rolled in place such as in the Hassam pavement. Further the physical bond thus secured between the stone particles is worth considering as an additional factor for strength and durability.

Difficulties of Repairing. Concrete is not easily repaired so as to be satisfactory. The difficulty of remedying a slight depression worn into the surface under traffic generally leads to letting such a defect increase to material dimensions before attempting its repair, which delay is of course objectionable. To repair any depression with any degree of satisfaction it has been found necessary that the depth of the hole be, or be made, sufficient to provide space for placing in it aggregate of the same size as that which forms the adjoining surfaces and flush with them. Also it is necessary that the new concrete be of uniform thickness, not tapering off at the edges. This means, that for the proper repair of a hole, the old concrete must be more or less cut away. Even then if a good bond is not secured between the new and the old concrete, the joints in the surface soon become objectionable. When the ordinary concrete roadway surface begins to need repair, it is practically only a question of a short time when the concrete surfacing will have to be abandoned as such, and turned into a concrete foundation because of the difficulties of repairing the concrete so as to leave it satisfactory as a road surface. If a concrete roadway is built with gravel, notwithstanding that the average greater strength of gravel concrete is greater than with broken stone concrete, the lack of mechanical bond obtainable from the rounded stones in the surface renders the latter particularly susceptible to damage by the shod feet of draught animals. The blow of a horseshoe may break the cementing mortar around a stone and the pushing or twisting of the foot may then easily dislodge the rounded stone from its place. Of course the adjoining stones are then more easily dislodged and the hole in the surface grows rapidly and needs repair. The difficulties of proper repair are so well recognized that many engineers are now recommending such work to be done with bituminous concrete instead of cement-concrete, but of course this is only a step toward the ultimate transformation of the concrete roadway into a concrete foundation.

Cracks and Joints. Again it seems pretty generally agreed that concrete roadways are liable to objectionable cracking under the influence of changes in temperature and in the conditions regarding moisture present. After being placed, the wet concrete shrinks considerably in setting and drying and this change of volume produces cracks in the surface. These cracks form points of weakness and foci of deterioration more or less serious according to their distribution and concentration. The effort is usually made to concentrate them in regularly occurring joints and these joints are often predeterminedly built in place with cumbersome iron or steel plates, which themselves are objectionable to traffic. These expansion joints increase in obnoxiousness as the road gets older and wears down, and ulti-

mately, in order to relieve this feature, if for no other reason, the coating of the whole road with a bituminous or other surface or pavement is necessary. If these expansion joints are not provided in the first place, the concrete roadway surface may develop cracks irregularly under alternate wetness and dryness or heat and cold, and these cracks break away on their edges and ultimately develop into objectionable places in the surface. Apparently the only remedy is to cover the entire surface with a carpet or pavement. The concrete roadway then becomes a concrete foundation, and if it can be foreseen, that such an end is probably to result within a limited time, reasons of economy demand its careful consideration before reaching a decision to attempt the concrete roadway construction in the first place.

Ease of Maintenance. Special machinery is not required for maintaining concrete roadways and in this respect they may have an advantage over such pavements as bituminous concrete and sheet-asphalt. Heaters, mixers, and unusual tools are not required nor even steam rollers for any but the largest repair jobs.

Cleanliness. Concrete pavements are fairly easily kept reasonably clean. They are perhaps less susceptible of dustlessness and thoro cleanliness, than is an asphalt surface or the best brick pavement, but on the other hand they are more so than macadam or even a good stone block pavement.

Resistance to Traction. This is extraordinarily low in the cases of concrete pavements, and few pavements lead them on this point.

Slipperiness. Concrete pavements are generally more slippery than macadam and stone block pavements, except perhaps in some cases of the latter where the joints are filled with cement mortar, but less so than wood block, bituminous pavements generally, and well laid brick pavements.

Sanitariness. Concrete pavements are slightly less sanitary than bituminous surfaces and pavements; are equal in this respect to the best laid brick; and are more sanitary than stone block pavements or macadam.

Acceptability. That is, the bases of personal or local preferences and of aesthetic consideration and of noiselessness. The glaring effect of the mortar in the concrete is frequently objectionable even when dark colored stone is used for the aggregate. On the the other hand, a light color of the concrete may be beneficial for unlighted roads thru woods especially where there is much travel at night. As to noiselessness, concrete pavements offer slight objections on this count. They are productive of more noise than bituminous surfaces and pavements or macadam, but of less than brick or stone blocks.

Favorableness to Travel. Concrete pavements are somewhat less favorable to travel than macadam or bituminous surfaces and pavements, and more favorable than stone blocks or brick in that their surface rigidity lies between the two types mentioned. An extremely rigid inelastic surface is objectionable to passengers traveling over it even when the vehicular devices for lessening the inevitable shocks are of the highest efficiency. Animals naturally prefer the softer materials on which to tread especially when unaccustomed to metalled or paved roads. As the proportion of surfaced to unsurfaced roads increases the latter objection to concrete will be somewhat reduced. Complaints from motorists using newly completed stretches of concrete roadways are that an unpleasant vibration was noticeable to the passengers in going over such roads, and it seems probable from the descriptions, that such vibration was due to minor unevennesses or corrugations in the surface unnoticeable to the eyes or at low speeds. If the speed is high enough, this vibration can be de-

tected on the best concrete roadways tho it seems imperceptible on macadam or on good bituminous surfaces and pavements. Those who lean toward concrete roadways may attempt to meet the objections by suggesting that the removal of nearly all grounds for objection and a considerable strengthening of the arguments for the more general use of concrete for roadways may be had by providing a bituminous surface on the concrete.

Concrete Pavements vs Concrete Foundations. Because of the difficulties, inherent with cement-concrete and incidental to its construction, of securing uniformity and homogeneity in the wearing surface of the concrete roadway; because of the initial extra cost for the proper results in many cases; because of its peculiarities, often offensive, such as high rigidity, dustiness, glaring color when new, or mottled color when repaired; and because of the difficulties and costs of repairs when needed; the proper selection of cement-concrete for a wearing surface is of limited application and the especial worth of this material in roadway work lies in its great value for foundations, on which carpets of various kinds may be satisfactorily and economically built and maintained. On the other hand, the high power of concrete to distribute over large areas of sub-grade the strains coming on roadway surface, and the adaptability of a cement-concrete roadway surfacing to its use as a pavement foundation when, under rapidily changing traffic conditions, such a transposition probably will be desired at an early period, justify, under certain local conditions, the selection of cement-concrete as the roadway surfacing. The far larger part of the consideration concerning cement-concrete pavements is composed of two main parts. First, the advisability of providing a concrete foundation for the surfacing, and second, the determination of the character, composition and thickness of the latter. It is interesting to note in this connection, the opinion of some eminent Australian engineers expressed (3) as follows:

"Within the last few years there has been much discussion of the question, whether concrete alone, without a wearing coat of any other material, can be advantageously employed for roadways for vehicular traffic or not, and widely different opinions have been expressed. Where Portland cement is very cheap, as in the United States of America, a rich mixture is warranted, and good results have been claimed, in some cases justly. Some leading engineers recommend 700 lb cement to each cu yd of concrete. There has been but little test of this material for this purpose in Australasia, and the few trial pieces have not, even when covered with a thin carpet coat of bituminous mixture, worn nearly well enough to be considered successful. In general, and especially when a wet mixture is used, the upper surface of the concrete will be mostly mortar, as the coarse aggregate tends to sink, and this mortar has generally been found too brittle to resist abrasion by horses' shoes and metal tires. A bituminous coat, say ¼ to ½ in thick, is not sufficient to take up the shock of traffic, and it generally peels off; then the mortar of the concrete is broken up and ravels, cups are formed, which are soon enlarged and, unless quickly repaired, the road goes to pieces. If the mortar of the concrete is particularly rich in really good cement, and the aggregate is both tough and hard, the surface will last longer. Another difficulty is the cracking due to changes of temperatures. Unless expansion joints are at pretty close intervals the concrete of the roadway is generally found to crack, this leading to the formation of ruts and grooves, which quickly increase in size by the abrasion of their edges. The same abrasion occurs at expansion joints, the filling in, which is necessarily plastic, so that for more reasons than one, road surfaces of concrete alone cannot, for general traffic, be said to have realized the expectations of a few years ago. Even if they had done so, the price of cement in Australasia has been, and is likely to be, too high to warrant their employment, except in special cases. For automobile traffic alone, with the general use of rubber tires, good concrete would be an ideal road crust, but the era of this condition is not yet, and for many a long day shod horses and steel tires will have to be reckoned with. Experience to date has undoubtedly shown that in road-making, the best use for cement-concrete is for foundation courses for wood

blocking, stone paving, or tough bituminous wearing coats, sufficiently thick to absorb the shocks of traffic and to prevent the disintegration of the concrete." See (24a), (24d), (28b), (34a), (35), (41) and (67).

"**Cement-Concrete Pavement Laid for Future Use as a Foundation.** (49c) The city recognized as its problem the construction of a pavement which would not only carry successfully all present traffic, but which, at some time in the future, could be utilized in connection with the development of the road into a city street, as the city was building up rapidly in this direction. Plans had already been prepared for such development, and called for a 66-ft street with 10-ft sidewalks and a 46-ft roadway. It was not thought desirable for the present, however to make the roadway pavement wider than 22 ft, which would be ample for a double line of traffic and allowance for turning out from one line at a time. This 22 ft was laid with concrete pavement, the top surface of which was made parallel to and 2 in below the middle 22 ft of the surface elevation proposed for the street pavement in the final development. When the growth of the city out this road may make it desirable to reconstruct it as a street, the present concrete roadway will be widened by 12 ft on each side, and the whole will then be used as a concrete base and covered with a 2-in layer of stone-filled asphalt. The present pavement is 6½ in thick which will be ample for a foundation for such a wearing surface, even tho it may have lost ½ in or so of material by wear in the meantime."

3. Subgrade

Consideration and the Proper Preparation of the Subgrade before placing the concrete, whether the latter is to itself provide the road surface or whether it is simply to act as a foundation for the roadway surfacing, is very important. In some cases, the roughest kind of preparation of the subgrade has occurred, it being argued that concrete, from its inherent qualities, will render unnecessary any careful work on the natural foundation under it. Economy and efficiency can only be had by carefully providing a suitable subgrade which shall be as even in composition as practicable, and be thoroly compacted and carefully trimmed to the required grades and cross-section. Sometimes the subgrade is rolled even where concrete foundations for pavements of various kinds were to be laid. Where the concrete layer is expected to be subjected to the effects of expansion and contraction, careful trimming up and smoothing of the surface of the subgrade is worth while in order to help minimize the effects of expansion and contraction of the concrete. A lateral movement of the concrete over the subgrade seems to take place, and unless the surface of the subgrade is sufficiently smooth to reduce the friction between the concrete and the subgrade material to such a low point as to permit this movement to be carried to the expansion joints provided in the concrete, there is danger of serious cracks occurring in the concrete between the expansion joints. Further, the proper preparation of the subgrade or base with regard to sufficient drainage is desirable, in order that the concrete layer may not be subjected unduly to strains arising through lack of proper drainage in the base. See (44). In California where much excellent concrete roadway surfacing has been laid, the subgrade is simultaneously compacted and planed just prior to the deposition of concrete on it. A template attached to and moved by the roller results in an unusually even and smooth subgrade which is at the same time made firm and compact.

The Report of Com. IV, 1914 Nat. Conf. Concrete Road Building, included the following recommendations:

"**Natural Subgrade.** The Committee calls attention to the fact that defects in the subgrade of a concrete pavement, or the improper preparation of it, may neutralize or nullify the care given to subsequent stages of the construction. The fundamental requirement of the subgrade is that it shall at all times be of uniform density, so that it will not settle unevenly and cause cracks in the concrete surface. Some engineers

apparently believe that it is not necessary to take as much care in preparing the subgrade or foundation of a concrete pavement as of other forms of roads having an artificial surface, because the concrete slab will act as a bridge over any soft streak or low spot in the foundation; but the Committee is of the opinion that this is a mistake. The strength of a plain concrete slab in acting as a beam to carry the load over a low spot or soft place in the foundation is very slight; and it is so easy to remove the low place or soft spot as not to justify the dependence upon the beam action of the concrete. Any uneven settlement of the foundation of a concrete pavement is nearly certain to cause a crack. With some forms of pavements a crack in the surface will heal under traffic; but a crack in a concrete pavement not only cannot heal under traffic, but will continually enlarge. There is no part of the work of the construction of a concrete pavement that is more worthy of intelligent care and painstaking labor than the preparation of the subgrade; and the slight additional cost necessary to insure good results is abundantly justifiable.

" **New Pavement on Old Road-Bed.** If the concrete pavement is to be constructed upon virgin soil, that is, if it is not to be constructed on an old road-bed, the precautions usually taken, which are described in the specifications to follow, are sufficient to secure a reasonably good foundation. But if the concrete pavement is to be constructed upon an old road-bed of any kind, either an earth or a broken stone or gravel road, great care must be taken in preparing the subgrade. The old road-bed is likely to be more compact in the center than at the sides; and consequently there is danger that the concrete pavement will settle more at the sides than at the center, and therefore will crack longitudinally. Further, it is likely that the travelled way of the old road will not at all places be central under the new concrete pavement, and consequently the latter will settle unevenly and crack. When the subgrade is an old roadway, it is not sufficient to roll the subgrade longitudinally, since the roller is likely to balance upon the more compact central core, and therefore not consolidate the soil at the side of the old roadway. It is not necessary to attempt a detailed description of the method of overcoming this difficulty; but the engineer should be alert to determine whether this condition obtains, and when it does occur, the necessary precautions should be taken to secure a thoro consolidation of all parts of the new road-bed. It may be necessary to add material at the side of the more compact central core of the old roadway. In extreme cases it may be necessary to loosen the old road-bed by spiking or scarifying, and then harrow it, and finally consolidate the entire new road-bed with the roller. The Committee desires to emphatically assert that the need of care in this matter is not imaginary, and that such conditions do really occur in actual practice.

" **Drainage.** The drainage of the road-bed of a concrete pavement is of vital importance. If the subgrade is not well drained, there is danger that, after the concrete is laid, the drying of the soil under the edges of the concrete may permit the pavement to settle and thus cause longitudinal cracks on the surface. Further, if the subgrade is not well drained, there is a possibility that the frost may lift the edges of the concrete roadway and cause a longitudinal crack, at least on the lower side and possibly also upon the upper surface of the concrete.

" **Sprinkling the Road-Bed.** Possibly the following item is more properly included in the instructions for laying the concrete; but it is mentioned here in order that it may not be overlooked. Before the concrete is placed, the road-bed should be thoroly saturated with water. This precaution is particularly important if the ground is dry or the soil is sandy.

" **Rolling the Road-Bed.** The road-bed shall be considered as that portion of the road upon which the concrete is to be placed. The road-bed shall be rolled with a three-wheeled self-propelling roller weighing not less than 10 tons, until every portion of it is firm and hard. When the natural road-bed is so sandy that no consolidation of the soil can be secured, the rolling may be omitted. If soft spots occur in the subgrade, they shall be dug out and the soft material shall be replaced with good earth or other material which will consolidate under the roller." See (50e).

4. Shoulders

There is almost a universal tendency in road construction to keep the width of the concrete low in order to reduce the first cost of the surfacing, and there seems to have been a neglect of proper consideration

of the matter of shoulders. This neglect, in many cases has unquestionably resulted in extravagances and waste in the long run, even if it has secured economy in the first cost. The shoulder maintenance costs generally form no inconsiderable part of the total maintenance cost of a modern road, and it is often real economy to build a pavement wider in order to keep down an annual expense for maintaining the shoulders. The actual width of the concrete roadway to be built should, as indicated in Sect. 4, be made with proper consideration of the traffic conditions to be expected on the road within a reasonable period. Where the concrete pavement is so narrow, that vehicles are almost constantly, in avoiding others, passing from the rigid concrete to the shoulder, serious wear of both the pavement and the shoulder will be found to take place along this line of weakness. This wear is frequently accompanied by the formation of a rut in the shoulder, which holds water in wet weather and thus endangers the foundation of the road. Some of the passing traffic will undoubtedly turn out on to the shoulder further than the rest, but at the extreme outside of the shoulder the travel over it may be so light and infrequent, that the natural material there is not strained beyond what might be called its elastic limit, and hence there is no reason, on this account at least, for its replacement at any extra cost.

The Selection of the Material and Methods for the Construction of Shoulders to a concrete road will therefore be seen to require the use of something between the natural soil, at the outside extremes, and the concrete itself; that the choices are determined by local conditions, such as availability of different materials and methods, width of the concrete road-crust, amount of traffic, etc; and that the wearing abilities or elastic limits of the shoulder material at any point should be outside or above the stresses to be expected at that point. The passage of traffic from the pavement to soft adjacent material can of course be absolutely prevented, and the protection of the edges of the pavement be had by the installation of a raised edging or curb as in the cases of most streets. The necessary reinforcement of the shoulder, where no raised curb is to prevent traffic on it, may be had in various ways. One would, of course, be to widen the concrete pavement to such an extent as to preclude any possibility of traffic going off it. In doing this the center thickness of the pavement need not necessarily be preserved to its edges but the thickness may be tapered down somewhat at the outsides. Or this widening, and tapering down in thickness, of the pavement may be done over a portion of what might otherwise be the shoulder and then the reinforcement continued by the use of macadam or pit-gravel or other materials as may be necessary. Again, the width of the concrete pavement being fixed, the shoulder reinforcement may be had by the construction of bituminous concrete, bituminous macadam, water bound macadam, with or without a bituminous carpet, etc, adjoining the concrete road, all as may be necessary and desirable under the local conditions. See (24b), (50h) and (50s).

5. Crowns, Grades and Thickness

Crowns. The axiom of road building that the flatter the roadway, the greater is the distribution of traffic over it, should be borne in mind particularly with concrete pavements, as their construction lends itself to the securing of low crowns. In the construction of concrete roadways, the effort should be made to secure the lowest possible crown consistent with proper shedding of the water from the surface to the sides of the road. As low as

$\frac{1}{16}$-in rise for each foot of width between the side and the center is generally satisfactory, especially where templates for striking the surface are properly used and the final trimming up of the surface carefully done. In no case, should the crown be permitted to be over $\frac{1}{2}$ in per foot, and even this maximum should be avoided where practicable. It may be difficult to secure as even and perfect a surface under the Hassam method as under the mixing method of laying the concrete, because under the former method, the use of templates is out of the question. Probably $\frac{1}{4}$ in per foot is as low a crown as can be satisfactorily secured under the Hassam method, without the occurrence of slight depressions in the surface which will hold pools of water. These water-holding places may not be in themselves objectionable, but their presence affects the condition of the concrete and can but result in lack of uniformity in its behavior under service. Often the crown and cross-section present the lines of two planes slightly rounded off at their intersection in the center of the roadway, but the provision of circular or parabolic arcs instead of these lines is better, especially in the cases of some city streets where considerations of appearance demand even more effort in this direction. The summit of the crown, or as it is sometimes called the crown, may be moved from the midway line of the roadway if necessary, because of different elevations of the footways on either side, or for other reasons. In the construction of the roadway by the Hassam method, the stone should be spread as in the case of macadam, so that the surface of the stone will form two planes intersecting at an angle. The rolling will then provide all the curvature necessary in the cross-section. Under the mixing method, the templates used will, with the final finishing, determine the curvature satisfactorily.

The Report of Com. XIII, 1914, Nat. Conf. Concrete Road Building included the following on Crowns: See also (50n).

"Unlike some types of pavements, those of concrete are undamaged by water, unless it should find its way to the subgrade. However, since even thin sheets of water or ice on the surface of any pavement are objectionable, a sufficient crown must be provided to insure the unwatering of the pavement. Theoretically, with perfectly surfaced concrete, only a very slight side fall is required to accomplish this. Practical experience in such construction, however, has demonstrated the great difficulty in preventing small imperfections and depressions in the surface, therefore sufficient cross-fall must be provided to insure drainage. The difficulty of accomplishing this is increased because of the suspension of large amounts of dust in the street water. Attention is directed to the fact that on city streets with side curbs we face a different problem from that found in a narrow country road without curbs. In the city street the crown must not only be sufficient to cause the water to run from the center to the side of the pavement, but also enough to insure that an undue proportion of the pavement shall not be covered with water. This requirement is aided if the pavement is given a peaked crown, that is, say $\frac{7}{8}$ of the total rise at $\frac{1}{4}$ distance from center to curb, and $\frac{5}{8}$ at half the distance. The small crown that may be properly used on concrete pavements is justly considered an important merit of this type of pavement. Data have been collected which seem to show that in the case of uniformly thick concrete pavements, the amount of central longitudinal failures has varied directly with the amount of crown. To a lesser extent this would be expected of the other types, thus furnishing an additional reason for the adoption of a minimum crown. In Appendix II will be found the practice regarding crowns in about 30 cities, from which it appears that the minimum crown used on streets is 1/160 of the width of the road and the maximum 1/48. With few exceptions, the crown varies between 1/70 and 1/100 of the width. When the climatic conditions will allow, a crown of 1/100 of the pavement width represents present best practice. The use of the high crowns has in large part resulted from past experience with other types of pavements where high crowns were really required. In future construction, as methods of handling materials are improved and contractors become more experienced, engineers should

not hesitate to specify as low a crown as 1/150 part of the width. Indeed, this has already been done to some extent.

"CROWN FORMULAS. The purposes of this report do not contemplate a discussion of the subject of crown formulas, but a few suggestions may not be out of place. The present common practice of specifying an arbitrary crown ratio for streets varying in width by 75 or more percent, and this, too quite independent of the street grade, does not appear to be founded on any reasonable basis. Unless local conditions forbid, a smaller crown should be designed for a heavy than for a light grade street. Tables have been published which give the allowable crowns as a function of the grades. This whole matter would seem to deserve much more attention that it commonly receives."

Grades. The Report of Com. XIII, 1914 Nat. Conf. Concrete Road Building included the following recommendations:

"The Committee have been unable to find any reliable data on the relative slipperiness of concrete pavements. It is greatly to be regretted that such information is not at hand. In view of the ease with which tests of this nature could be made and the importance of such knowledge in the design or selection of pavements, we recommend to this convention that experiments along this line be undertaken, perhaps such work can best be done under the guidance of some University because of the need of unbiased and impartial tests.

"From such observations as we have been able to make, we see no reasons why a concrete pavement, properly finished, may not be used on grades as steep as any other hard surfaced pavement, and on steeper grades than either wood or asphalt. On steeper grades than 3 or 4% shallow corrugations in the surface will be found of much assistance, in fact, with grades of 5% and over, a real necessity." See (50a).

Thickness. The Report of Com. XIII, 1914 Nat. Conf. Concrete Road Building, included the following conclusions:

"The thickness of the concrete pavement is controlled by many factors, such as condition and character of the subgrade, drainage, traffic, climatic conditions, width of pavement, etc. Three distinct types of cross-sections are in general use.

1. Uniform thickness of concrete for all widths of roadway, and consequently with the same amount of crown in the foundation as in the surface.

2. Roadways in which the concrete is thicker at the center than at the edge but in which some crown is given to the foundation.

3. Concrete roadways in which the concrete is thicker at the middle than at the edge, but which are built upon a flat subgrade. This type seems to be fast gaining in favor.

For a table giving data on the thickness of concrete pavements in this country and some additional information on thickness, see (50n).

"It will be seen from these data that the thickness of concrete pavements varies from 6 to 8 in at the crown line and from 5 to 8 in at the edge. The necessity for the greater thickness is perhaps more urgent in the northern than in the southern parts of the United States, because of the greater extremes of temperature. Because of the growing tendency to increase the size of the loads, it seems reasonable to suppose that the extreme limit of thickness required has not yet been reached.

"Because of the fact that the members of this Committee have had their attention directed chiefly to the conditions obtaining in the northern states, it is not without some misgivings that they suggest the following as conforming to the best practice.

1. Where the width of roadway is not greater than 16 ft, with a porous subsoil, subgrade in good condition and well packed and with loads not exceeding 6 tons, including the vehicle, a thickness of 5 in at the edge of the slab and 7 in at the center is sufficient without reinforcement, using slabs not greater than 16 ft square.

2. On clay soil and the above general conditions, artificial drainage should be provided and reinforcement, ¼ to ½ lb per sq ft, used, placed 1½ to 2 in from top surface; and slabs made not larger than 16 ft square and not less than 6 in thick at edge of slab and 8 at the center

3. Where the roadway is in excess of 16 ft with loads of 6 to 10 tons but with the other general conditions as described in (1), the crown of the pavement should have a thickness of 8 in and the edge 6 in. Under such circumstances reinforcement will usually be considered necessary and economical." See (50n).

Some Tests in Connection with Thickness were made by the Cal. State Highway Comm., especially as regards the abilities of a concrete slab to span successfully under loads trenches or depressions in the subgrade. For a statement concerning these tests and their results, see (49a).

The Relative Advantages of Flat and Crowned Subgrades is a subject of much discussion, but is determined by local conditions. See (29).

MATERIALS

6. Quality of Aggregates

Broken Stone, Gravel and Slag. Broken stone or gravel form the principal coarse aggregates for concrete for road purposes, tho occasionally slag is used. With the use of slag, care must be taken that it is of suitable quality, some slags being so soft and friable as to be unsuitable even when the concrete is acting mainly as a foundation. Some other slags, however, are equal in every respect to the better grades of broken stone, in some cases even making a stronger concrete than the stone, because of the apparent affinity of the slag for the cement. See (28d). Generally in the use of slag, more water is required than in the case of broken stone for making the mixture of proper consistency. The choice between the use of broken stone and gravel depends largely on local conditions. Ordinarily, gravel when mixed into concrete will produce a concrete of slightly greater cross-breaking and crushing resistance than broken stone, probably because the rounded particles of the gravel permit and result in a denser concrete in the ordinary methods of the mixing and placing than is obtained with the angular fragments of broken stone. A mixture of 35 to 50% gravel with 65 to 50% of broken stone will, under the ordinary mixing methods, give an even stronger croncrete than either gravel or broken stone alone, probably for the same reason, and coarse gravel which has been run thru a crusher and thus broken up to some extent, will give a concrete about equal in strength to the mixture of gravel and broken stone referred to above. Tests made in the laboratory of the Md. Geol. Survey in 1905 and 1906 on 4 in concrete cubes made from mixtures in the same proportions of sand, cement and broken stone, the same sand, cement and gravel, and the same sand, cement and a mixture of the gravel and broken stone, showed the ultimate crushing strength to be in the order named, and furnished the foundation for the foregoing remarks. If the concrete is made of gravel and is exposed directly to the traffic, the tendency of the rounded gravel stones to be dislodged from the mortar surrounding them has been noticed, and this seems to exist to a greater degree than is the case with angular broken stone. On the other hand, the gravel being usually made by natural forces from the harder varieties of rock, generally exhibits a greater resistance to wear than many of the rocks crushed and used for concrete. See (28c) and (50d). Slag and trap rock concrete gave under comparative tests at Columbia Univ. an average compressive strength of 2465.5 lb per sq in for the slag and 1975.5 lb for the trap rock concrete.

The Report, Com. III, 1914 Nat. Conf. Concrete Road Building (50c) **was, in part, as follows:** "Tentative specifications for aggregates are given at the end of the report. Simple rules covering the most essential requirements are as follows:

1. For fine aggregate, use only sand or other fine aggregate that has been actually tested for mechanical analysis and tensile strength of mortar, and is free from fine particles.

2. Use coarse grained sands or hard stone screenings with dust removed.
3. Use sand or other fine aggregate that is absolutely clean.
4. For coarse aggregate, use hard stone, such as granite, trap, gravel, or hard limestone.
5. If bank gravel or crushed stone is used, always separate the sand or screenings and re-mix in the proper proportions.

"If local conditions prevent following any one of these rules, adopt some other material than concrete for your pavement.

"Briefly taking up each one of these points:

1. Actual laboratory tests are necessary for fine aggregates, because it is impossible for the most expert builder to always distinguish by appearance between good and poor sands. Sand may be coarse, of good color, well graded, and apparently perfectly clean, and yet because of a minute quantity of vegetable matter may show practically no strength when made into mortar or concrete. See (20a).

2. Coarse sand is necessary not only for strength and density, but to prevent the formation, on or near the surface, of a layer of fine material, consisting of a mixture of dust and cement which has no durability. Mortar made with fine sand or sand having a large proportion of fine grains of silt, hardens slowly and is especially objectionable in cold weather. This prevents its attaining proper strength before the road is thrown open to traffic. A sand having a considerable proportion of fine particles may possibly show high briquette tests, and yet the mortar not have good resistance to attrition or wear.

3. Sand must be absolutely free from vegetable or organic matter, or it is liable to harden not at all or too slowly to be serviceable. Frequently, sand may be entirely satisfactory in appearance, and yet be worthless for concrete.

4. A coarse aggregate of hard quality is necessary to resist the wear and abrasion of hoofs and wheels. Failures of concrete roads have been caused simply by the softness of the coarse aggregate. In one instance, for example, shells were used for the aggregate, and the road went to pieces as soon as it was subjected to wear. See (60). All stone, like shale, slate, shells, and soft limestone, must be rejected; while trap, granite, and conglomerate, are especially suitable materials. A hard limestone, such as that occurring in certain localities along the Hudson River, which is sold in New York as trap rock, is satisfactory for concrete roads. A hard limestone cannot be cut with a knife and the specific gravity is high, say, over 2.70. Gravel does not bond quite so strongly with cement as does broken stone. When properly screened and free from dirt, however, and remixed with sand in the proper proportions, a good surface can be made even for a 1-course pavement.

5. Many roads that are now being built will prove worthless because of the use of sand taken directly from the bank without screening. If the gravel contains as much as 40% of stones and very rich proportions are used, say 1 part cement to 3½ parts bank gravel, a fair concrete can sometimes be produced, but it is always cheaper in such cases to screen the gravel and remix the sand and stone in proper proportions. There will be, for example, a saving of ¼ barrel, or 1 bag, of cement per cubic yard of concrete by using proportions 1 part cement to 2 parts sand to 3 parts screened gravel, instead of using the unscreened bank gravel in proportions 1 to 3½. This difference will more than pay for the additional cost of screening the sand and rejecting part of it. At the same time, the result will be more uniform and the surface more durable because of the stones which take the wear. When an excess of sand is used in the mixture, as is the case with run-of-the-bank gravel, the mortar rises to the top when the concrete is placed and the wearing surface is less resistant than a mix that is uniform thruout."

7. Proportions of Aggregates

Various proportions of the aggregate, cement and water are used or contended for. In the majority of cases, some arbitrary formula is generally followed, but this practice is of extremely questionable value. If it is to be expected that within a relatively short period, the concrete roadway is to be covered with a bituminous carpet, or other protecting surface, there certainly are serious objections to providing a richer and more ex-

pensive mixture and to using a larger proportion of cement than is necessary to give sufficient crushing and cross-breaking resistance in the concrete under the loads to be carried by the concrete as an artificial foundation. On the other hand, if no protective coating is to be provided on the concrete, it may be necessary to make the mixture sufficiently rich in cement, as will enable it to resist to the utmost the destructive effects of traffic coming directly on it. Between these two extremes, various proportions in the mixture are possible, and the exigencies of the particular case should be carefully considered when the decision as to the proportions is to be made. Further, with regard to the amount of cement to be used in any case, it is now generally recognized that the carrying power of various materials for cement, differs considerably. That is, some kinds of material require more cement in the mixture to give the same strength than do others, and a similar remark may be made in regard to the cement itself. Some cements seem to go further than others when used with the same aggregates. For concrete pavements exposed directly to traffic without the protection of a carpet of any kind, as much of the coarser aggregate as possible should be secured in a given area of surface of the road, in order that the greater part of the wear from the traffic shall be borne by this aggregate and not by the mortar or cement. On the other hand, where the wear of traffic is to be taken up by a carpet and the concrete layer is to act mainly as a foundation for the carpet, the proportion of coarse aggregate should be that which will give the greatest sustaining power to the concrete mixture, regardless of the grinding or hammering effect of the traffic. Reference to Sect. 2 will be advisable in this connection for information concerning the manufacture of hydraulic cement and its characteristics. N. C. Johnson (42), gives important information concerning concrete, thru the use of microscopic tests demonstrating conclusively the need for proper mixing of the ingredients, proper hydration of the cement and proper proportions for all of the materials used, and pointing out that an excess of cement not only does not add proportionately to the strength of the concrete but actually weakens it in many cases. This is particularly true where concrete is used for roadway surfaces. See also (24c), (50o) and (69b). The amount of water necessary for concrete road construction will of course depend on local conditions, weather and other factors. It has been variously estimated, at from 50 to 250 gal per cu yd of concrete. See (26d) and (50l).

Hydrated Lime is sometimes added in the mixing or used to replace a portion of the cement that would otherwise go into the mixture, and the amount of lime so used is generally about 10% of the amount of cement. The addition of hydrated lime to Portland cement mortar or concrete is not new, but the application of the idea to some forms of concrete work has not been given as much attention as necessary to develop all the possibilities. The waterproofing feature of the addition had been dwelt upon to some extent but the other apparent advantages to be had from the addition, such as those coming from the increased plasticity of the wet concrete, have generally been ignored. See also (8), (14), (34b), (65) and (68). Where concrete is to be delivered by the spouting method the low angle of slope requires an excessively wet concrete to insure easy spouting, and yet excessively wet concrete is undesirable for many reasons. The addition of hydrated lime, by its giving the greater plasticity to the concrete, reduces the necessity for water in excess, and would in many cases permit of satisfactory spouting of the concrete on a flatter slope. Another point in favor

of the use of lime in concrete pavements is an apparent effect of the hydrated lime to reduce the tendency to segregation in the wet mortar of sand, cement and stone. A further effect of the addition of lime and one particularly appreciable in highway work is the reduced susceptibility of the resulting concrete in the matter of expansion and contraction of this mass, and therefore a reduction in the cracking so often objectionably evident in concrete roadways. In laying a concrete roadway, it is important to have the concrete wet enough to permit its being readily and properly compacted to form a mass with a minimum of voids, and yet when so wet to avoid segregation. The addition of hydrated lime seems to decrease the tendency of the cement and sand to separate and at the same time to make the mass more readily compact. Lime mortars are usually softer than cement mortars, and there is some question, which can only be answered by experience, whether or not the addition of the lime will result in an unsatisfactory degree of hardness in the mortar for concrete roadways, especially as extreme hardness and resistance to concussion and abrasion are of greater importance for the concrete in roadways than in most other places where it is used. Thoro mixing of hydrated lime with the cement is important as otherwise a lack of homegeneity with its highly unsatisfactory consequences will result. See (27a) and (36).

Density and Strength. The proportions of the various ingredients should, in order to give the greatest possible strength to the concrete roadway, provide the greatest density for the concrete. With the use of varying kinds of aggregate, it will then be necessary, in order to secure the greatest density, to determine accurately the irreducible voids in each kind of aggregate and to proportion the ingredients accordingly. That is, the voids in the fine aggregate should be accurately determined and sufficient cement provided to fill the voids. Usually it is best to allow a slight, say 5 to 10%, excess of cement for the actual voids to be filled so as to make up for any unavoidable loss or waste in manipulation. Having determined the irreducible voids in the coarse aggregate, provide such an amount of mortar as will fill these voids, also allowing a slight excess in the mass of mortar for the voids in the coarse aggregate. Any use of hydraulic lime may be considered either as part of the cement to be used or as the excess of cement referred to.

Moyer (47) states that "Maximum density, other things being equal, gives maximum strength. Arbitrary specifications, without previous knowledge of the character of aggregates to be used, are wrong, and the stated proportions are meaningless. Various sizes of stone should be used for purposes of economy and for obtaining the greatest density and strength." See (12), (13), and (49b).

The Usual Practice in Making a Mixture is to assume arbitrarily certain proportions for the cement, fine aggregate and coarse aggregate, and in most cases to use far more cement than is necessary or desirable.

The Report, Committee XIV, 1914 Nat. Conf. Concrete Road Building included the following: See also (50o).

Variations in Local Conditions. "Any specification for proportion and consistency of materials for concrete pavement must be general and suggestive, rather than mandatory, adaptive, or rigid. The representatives at this conference come from all parts of the country, from districts whose geological formations furnish concrete materials differing widely in their physical and chemical composition, and also furnish soils of equally wide characteristics upon which these pavements are to be laid. A rule that may be admirable for a granite district, furnishing hard cubical well graded rock, may fail utterly if applied to a district whose only resource is soft limestone or gravel that washes into shape instead of fracturing into sharp angled cubes. Ideal paving concrete is a combination of perfect mineral aggregates and cement in such proportion

as will give the greatest possible density, and in which, for economical considerations, the cement content is the least possible consistent with ultimate strength and durability. Relative cost of material may justify greater thickness of base with less crushing or tensile strength per unit area.

Proportions of Ingredients of Concrete. "For the base of TWO-COURSE PAVEMENT, with sound hard limestone or gravel having 40% voids, screened washed bank sand having 30% voids, and Portland cement passing the standard specifications of the Am. Soc. Test. Mat., the proportions should be 1 sack of cement, 2½ cu ft of sand and 5 cu ft of crushed stone or gravel, the aggregate having been so proportioned as to eliminate the voids as far as practicable.

"For ONE-COURSE PAVEMENT the proportions should be 1 sack of cement, 2 cu ft of sand and not more than 3 cu ft of crushed stone or gravel.

"**Consistency of Concrete.** The amount of water should be such as to make the concrete plastic and still retain its shape, such as is commonly called a quaking mixture. Methods and distance of transportation before depositing will be factors in determining the amount of water used. Concrete deposited from buckets, travelling along a boom, may have more water added than when wheeled for a considerable distance in barrows or carts. In the latter case, the unavoidable shaking brings the lighter materials to the surface and causes a segregation of the materials, which results in an improper mixture when deposited.

"**Proportions of Wearing Course.** The fine aggregate for wearing course shall be mixed with Portland cement in the proportion of 1 sack of cement to 2 cu ft of the graded mineral aggregate. While this furnishes a considerable excess of cement, greater impermeability is secured.

"**Consistency of Wearing Course.** Sufficient water shall be used with the fine aggregate to form a mortar that will work easily under the template and at the same time retain its shape when deposited."

8. Mixing Cement-Concrete

Mixing the Ingredients for the Concrete in a Machine designed for the purpose and then placing the prepared mixture on the subgrade made ready to receive it so as to give the thickness, grades and cross-sections desired, is at present the more usual method of constructing concrete roadways. Attempts have been made to roll the concrete after so placing, and they have been more or less successful. See Art. 14. Various makes of machines for mixing the concrete and different contrivances for conveying it from the machinery to the road-bed are in use, each claiming some special advantages. The desirable points for such machines are uniformity of mixing, rapidity of work consistent with uniformity, ease of cleaning, convenience of operation and reasonable cost of operation, and ease of movement from place to place on the road. For conveying and placing contrivances, it is necessary that they be flexible, and that they shall prevent, insofar as practicable, any tendency of the concrete mixture to segregate.

The Report of Committee XI, 1914 Nat. Conf. Concrete Road Building includes the following recommendations: See also (501).

"In the construction of concrete roads, probably no really important part of the work is given less consideration, in specifications and in the field, than the actual mixing and placing of the concrete. The following notes, based upon observations in field, and the results of tests, were prepared with a view of pointing out the difference between good and bad practice, and to serve as a basis for recommendations covering this phase of the work.

"**The Mixer.** The concrete mixer should be of the batch type provided with an automatic water tank, traction drive and power loader. Mixers having a boom and bottom dump bucket of sufficient size to convey one complete batch for placing the mixed concrete, are preferred. However, buckets of other types and sizes, open troughs and revolving tubes can be used, and will give good results. An abuse of the

revolving tube distributing method lies in operating batch-mixers so equipped as continuous mixers, the supposition being that as the tube is provided with blades and revolves, the materials are mixed in the tube. This tube serves only as a conveyor and cannot to any degree take the place of or serve as a mixer. Concrete cannot be successfully conveyed or delivered thru a trough or spout, thru which it must flow by gravity, for if it is mixed to a consistency such that it will flow at the required angle, the concrete will be too wet for the best results. The mixer should be provided with a suitable automatic water tank which can be quickly filled and emptied, so that when once determined, the required amount of water can be added to each batch of concrete. A number of so-called automatic tanks on mixers are not satisfactory owing to their limited capacity, delay in filling and emptying, and to the fact that they depend, for successful operation, upon a constant water pressure. Water is pumped on most road jobs, with small gasoline or steam pumps, and it is not possible to maintain uniform pressure in the feed line. An automatic measuring tank of the required capacity, that may be emptied quickly, connected by means of a comparatively large pipe, with an auxiliary or storage tank of about 50 gal capacity, would be more satisfactory than the one tank system commonly used. Where necessary to keep from cutting up the subgrade and to facilitate moving, the wheels of the mixer should be run on suitable planking. Material of good quality, 3 in thick by 10 in wide, in comparatively short lengths, with square ends, will be found satisfactory for this purpose. The power loader or skip should be of sufficient size to hold all the materials required for the batch. In charging the skip a part or all of the coarse aggregate should be placed first, and the cement, fine aggregate, and remaining coarse aggregate, if any, on top of this. All the cement should be in the skip before the last of the aggregate is added. If charged in this manner there will be less tendency for the materials to stick in the skip when emptying and less loss of cement on windy days. A systematic method of loading the skip will also serve as a check on the right amount of material being placed each time. The filling of the skip is accomplished in practice in two ways; by the use of wheelbarrows and by shoveling direct from the supply piles into the skip. This latter practice, however, should be discouraged, for accuracy is impossible, and it encourages carelessness. Besides, the entire loading gang loses time waiting, while the skip is raised and lowered.

" Mixing Concrete. No important operation is given less attention than the mixing of the concrete. Frequently in practice, the time the materials remain in the drum is governed only by the speed of the gang charging the skip. At times the batch mixer is operated practically as a continuous mixer, by fastening the discharge scoop or spout so that there is a constant flow of concrete from the mixer. The quality of concrete is largely dependent upon thoro mixing. To insure thoro mixing, the revolutions per minute of the mixer and the time the complete batch, including water, remains in the mixer, should be specified. To specify either the revolutions per minute or the time, is not sufficient as is plainly shown by the following tabulations of field observations:

Job	Mixer	Rev per Min	Mixing Time
1	Smith	10	1½ min
2	Koehring	18	40 to 45 sec
3		18	30 sec
4	Foote	14	45 sec
5	Eclipse	13	2 min
6	Austin Cube	16	50 to 55 sec
7	Smith	11	2 min
8	Chicago	24	30 sec
9	Foote	18	25 sec
10	Koehring	18	20 sec
11	Austin Cube	16	20 to 60 sec
12	Koehring	32	15 sec
13	Austin Cube	16	10 sec
14	Ransome	7	1 min
15	Koehring	18	20 sec

"Upon inquiry of the manufacturers it was found that the revolutions per minute of the drum of batch mixers varies for different makes and for different sizes of the same make, as shown by the following table compiled from data furnished by the manufacturers:

CAPACITY AND SPEED, REVOLUTIONS PER MINUTE, OF PAVING MIXERS

Name of Mixer	Rated Capacity Cu Ft Unmixed Material	Capacity Bags of Cement in 1 : 2 : 3 Mix	Rev per Min of Drum	Name of Manufacturing Co.
Austin Cube	14	2	18	Municipal Engineering & Contracting Co.

	15	2	18	

"Because of the shape and arrangement of the interior of the drum, the rate at which a given mixer is operated has a direct bearing upon the quality of the concrete, therefore the drum should be operated at approximately the speed at which the manufacturer claims the best results would be obtained. It is recommended that all specifications contain a clause to the effect that all the materials in any one batch, including the water, should remain in the drum of the mixer at least 45 sec before any of the concrete is discharged. In all cases the drum should be completely emptied before the next skip of materials is dumped into the mixer. This is a source of constant controversy between the engineer or inspector and the contractor, especially where the mixer used is equipped with an open trough, or with a boom and bucket when the bucket is not large enough to hold the whole mixed batch. The operator should start the water into the drum as soon as the skip is in position to dump, that is, it is not necessary to mix materials dry before adding water. See also (50 l).

" Consistency. The practice on road work is to mix concrete entirely too wet. This causes a separation of the coarse materials from the mortar, resulting in stony pockets thruout the concrete. Where the concrete is mixed too wet, it is practically impossible to obtain and hold the required crown, and stony patches frequently appear on the surface after it has been finished, owing to the flow of water and mortar to the sides. In striking off and floating concrete mixed with an excess of water, it is also practically impossible to obtain a surface of the desired character, as the excess of water collects in and hides depressions and other inequalities in the surface, which

cannot be corrected as they are not apparent until after the water has evaporated. In addition to the difficulty encountered in getting wet concrete into the pavement in a manner which will give the best results, laboratory tests and results observed in the field show that, other things being equal, a wet mixture is of inferior strength and quality to concrete of a medium wet consistency. The marked effect in the strength of concrete that a variation in the consistency produces, is shown in the following table of results of tests made in the Sheffield Scientific School of Yale Univ. by Robinson. See (54).

Percent Water	7 Days†	30 Days*	60 Days†
20.	2052	2777	3194
22½.	2173	3132	3305
25.	2277	3278	3388
27½.	2500	3516	3597
30.	1722	2874	3166
32.½.	1413	2416	2666
35.	1222	1977	2388
37½.	1097	1819	2173
42½.	652	1500	1888

*Average of two tests. †One test only.

"In this test water was added from 20 to 42% according to the following method: As a minimum, enough water was taken to moisten the stone and sand, and then there was added 20%, of the amount of the cement by weight, water. Each subsequent mixture was increased by 2½% water. It was noted that the 42½% mixture was about as wet as is used in the average wet mixture, tho drier than some slushy mixes.

"As yet, there is not sufficient data on which to base a definite conclusion relative to the influence of the consistency of concrete upon the expansion and contraction; however, information at hand seems to show that this action is influenced very largely by the consistency. Owing to the methods employed in striking off and finishing the surfaces of concrete pavements, there is little likelihood of mixing the concrete too dry. Concrete mixed with an excess of water is easier to mix, to handle, to place and to finish, than concrete of the proper consistency, which explains the tendencies toward wet mixtures. The amount of water in the concrete should be such as to cause it to settle to a flattened mass when dropped from the bucket, but not sufficient to cause it to flow readily on the subgrade. The consistency should be such as not to require tamping, but not so wet as to cause a separation of the mortar from the coarse aggregate in handling and placing. If there is an excess of water on the surface, or the mass has a tendency to flow or settle out of position after being floated, the concrete has been mixed too wet."

The Report of Com. VIII, 1916 Nat. Conf. Concrete Road Building (50 l), says . . . "your Committee believes that with the average amount of moisture found in concrete materials, the water to be used in a proper mix for concrete used in road making should not exceed 6 lb per cu ft of material, this meaning the cement, sand and stone used, measured loose. This is approximately 1 gal of water for each cubic foot of concrete in place. Dry materials in hot weather require more water, and rain soaked sand and stone require less water. The most needed reform in the mixing and placing of concrete for roads is less water than is generally used."

Proportion of Water. Fletcher correctly states that a variation in the proportion of water used in the mixes is largely responsible for inequalities in both the character of the concrete and its evenness of surface, and that no matter what mechanical contrivances exist for controlling the supply of water in the several batches, the operation of the machines will vary and the results will be unsatisfactory. Ponding for curing the concrete is therefore advocated as effective for curing and also for compensating the inequalities of the water in the different mixtures. See Art. 14.

Duration of Mixing. Uhler states (68) that "Every batch of concrete is mixed for 1½ min; the reason for this being that a number of experiments, made during the progress of the work, indicated that the greatest strength, commensurate with economy in cost of mixing is obtained from a mix of this timing. The experiments which resulted in this conclusion were as follows:

½ min mix, 9 rev, 8 day test, 1400 lb per sq in,
1 min mix, 17 rev, 8 day test, 1587 lb per sq in,
1½ min mix, 26 rev, 8 day test, 1924 lb per sq in,
2 min mix, 35 rev, 8 day test, 1661 lb per sq in,
3 min mix, 51 rev, 8 day test, 1673 lb per sq in.

This shows that if these results are plotted, the curve would break between the 1½ and the 2-min periods. If the accuracy of the results on the 1½ min mix be questioned, and this figure assumed to lie between 1587 and 1661, the results plotted so as to form a curve will show that the rate of increase in strength decreases with increase in the time of mix, and the increase obtained from the 2 and 3 min periods is scarcely worth the additional time and cost involved."

9. Tests of Cement-Concrete for Pavements

Essential Properties. The most important requirement in concrete for roadways is uniformity, and this is also one of the most difficult to obtain. In the operations of mixing and placing concrete, there is always present a tendency toward segregation of the mortar and different sizes of aggregate which results in pockets, or areas of different composition thruout the concrete layer and more especially in its surface. It is evident that the resistance to the effects of traffic will be unlike in different areas, and a serious danger exists of lack of uniformity in wear. The results of non-uniformity are holes in the surface and irregular cracks thru the mass. This means that the surfacing of the worn concrete with other materials will have to be begun at an earlier date than would otherwise be the case if uniformity of wear were had, to say nothing of the increased cost of repairs to the original surface in the meantime. See (59). High resistance to the forces tending to produce expansion and contraction in the concrete is another desirable quality in the concrete roadway. This is especially important where the concrete is not covered by a protective coating and the forces referred to have the greatest opportunity for action, while the effects of such action are also most appreciable. It is believed that the greater the density of the concrete, the higher the resistance to expansion and contraction. An effort has been made to test concrete for the qualities involved in its use for roadways at the University of Minnesota, but the machine used in the test has not been standardized, nor has the work with it progressed far enough to show its qualifications sufficiently to recommend its adoption for standard testing purposes. See (43).

Field Samples of Cement-Concrete. Method recommended by First Conference, 1917, State Highway Testing Engineers and Chemists.

"**When Taken.** Samples shall be taken regularly, for the general control of strength and uniformity on 1 day of each week of work; and at irregular intervals, whenever a complete change is noted in the character or grading of one or more materials or in any element affecting the entire mix.

"**Number of Samples.**

1. In taking regular samples three specimens should be molded to be broken one at each of the periods, 14 days, 28 days, and ....

2. In taking irregular samples, nine specimens should be molded, three to be broken at each of the periods, 14 days, 28 days, and ....

"**How Taken.** The batch sampled for general purposes should be similar in consistency and general grading of the aggregate to the regular run of batches being turned out. The sample from which specimens are molded should be composed of several portions taken during the discharge of one batch in order to represent an average of the batch; or the batch may be dripped upon the subgrade and concrete from several points, taking care to exclude dirt, placed in a clean wheelbarrow or other container, avoiding additional mixing."

Tests of Field Samples of Cement-Concrete. Method recommended by First Conference, 1917, State Highway Testing Engineers and Chemists.

"**Form of Specimen.** The test specimen may be a cube, a prism or a cylinder, but it is felt that a cylinder 6 in in diameter by 12 in high will give the most satisfactory results. Molds of all types can be successfully used, from the most permanent to those which can be used only in forming a single specimen.

"**Molding Specimens.** The molding should be done as near the mixer as practicable, and the concrete should be conveyed to the molds with as little jarring or mixing as possible. The molds should be placed on a flat, non-absorbent surface, and the concrete should be placed in layers of .... inches, with slight puddling by means of a ½-in steel rod.

"**Storing.** Specimens should be permitted to remain in position where molded for a period of 24 hr. At the end of that period they may be stored on the completed concrete pavement, buried in the same covering material, and moistened at the same intervals, until ready for shipment to the laboratory; or, if not considered practicable to store on the completed concrete, they may be covered at the point of molding with the same covering material as used for the concrete pavement, and moistened at the same intervals, until shipped to the laboratory.

"**Shipment.** Specimens must be suitably protected from injury during shipment.

"**Testing.** Specimens should be capped with mortar shortly after molding, or with plaster of Paris just before testing, so as to provide plane bearing surfaces. The plane surface is formed by placing the specimen on a flat, non-absorbent surface and pressing a flat plate on the soft mortar or plaster cap. In testing, the specimens are mounted in the testing machine with spherical bearing block placed on top of the specimen, the capped specimen being placed in direct contact with the steel bearing surfaces.

Compression Tests. Uhler states (63) that "Another feature that has been brought out in connection with this work is the great variation in strength of 6-in cubes of the regular mix, made up daily during the progress of the work, and set aside for testing at periods of 7, 14 and 28 days and 6 months. The 7-day compression test runs from 1065 to 3635. The 14-day test, from 1572 to 4212. The 28-day test, from 2862 to 5361. As yet, no 6-month breaks have been made. These wide variations in strength values may be due to a combination of several causes, including variations in the quality of the cement and mineral aggregates; difference in storage temperature, some of the specimens having been made up during warm weather and some during very cool weather; possible slight differences in the mix, and differences in the molding and compacting of the specimens; and finally, the unavoidable experimental variations in making and breaking the specimens. Since every one of these factors, except the last named, enter into the actual construction work, the importance of systematic testing of the cement used, examination of the sand and stone, particularly with reference to grading, and strict adherence to uniform, approved methods of mixing, placing, compacting and curing the concrete in the pavement, are forcibly demonstrated by the range in these daily strength values."

Rattler Tests by Roman (58). "The experiment consisted of preparing blocks of concrete, mortar and cement of a standard paving brick size, 3½ by 4 by 8½ in, and submitting them, when 90 days old, to the rattler test for paving brick. The same cement was used in the preparation of all of the blocks, and the same sand was used in the mortar and concrete blocks. The quantity of water used was such as to give a cement paste of normal consistency for the cement blocks, and such as to give mortar and concrete which could be floated without tamping, but which were not so wet that they would flow readily. The mortar blocks were made of 1 part cement and 2 parts sand, and the concrete blocks of 1 part cement, 2 parts sand and 3½ parts gravel or crushed stone. All measurements were by weight. The blocks were kept under wet sacks for 1 week and after this period they were sprinkled with water once a week. The blocks were all tested in the rattler at the age of approximately 90 days, after they had been air dried for 1 week. The rattler used was a standard paving brick rattler as recommended by the Nat. Paving Brick Mnfrs. Assn., rotated at the rate of 30 rev per min. Ten blocks were taken for each test and a standard charge of 300 lb of cast iron shot used. In order to follow closely the effect of this abrasion test, all the blocks were submitted to repeated rattler test of 900 rev each. Ten paving bricks, representing 5 brands of blocks used on State Aid roads in Illinois, were submitted to a similar test. Each block was marked in such a way that it could not be identified during the entire experiment.

"While no definite conclusions can be drawn from these tests as to the relative wearing qualities of brick and concrete, yet the results obtained appear to bring out the following facts, which have a bearing on concrete road construction:

1. The advisability of using rather small aggregates in one-course concrete road construction. This will tend to insure more uniform wear and a smoother surface.

Table II.—Showing Total Losses in Percent by Weight of Blocks

Revolutions of Rattler	900	1800	2700	3600

NOTE. D No. 1, and D No. 2, Danville Blocks; P No. 3 and P No. 4, Poston Pavers; A No. 5, and A No. 6, Albion Shale Blocks; S No. 7, and S No. 8, Springfield Blocks; B No. 9, and B No. 10, Barr Blocks.

2. The apparent advantage as far as wearing qualities are concerned of the 2-course method in concrete road construction. A rich mortar or fine aggregate concrete could thus be used for the surface course, insuring much better wearing qualities. At the same time, a lean concrete, or aggregates of rather poor quality, could be used for the lower course and the resulting cost of the road would probably be less than the cost of the one-course concrete pavement, as built at the present time.

3. The disadvantage of using a very wet concrete or of excessive floating of the concrete, both of which have the effect of bringing to the surface of the road a layer of neat cement. The above tests show that neat cement will not stand impact and will rapidly be worn off under traffic. It seems probable that some of the depressions which form on concrete pavements are due to the wearing of neat cement as well as to the formation of stone pockets."

Rattler Tests by Abrams (11). "The machine used is a brick rattler of the Talbot-Jones type. The concrete tested is molded into blocks with square, 8-in faces and depths of 5 in. The 10 blocks constituting a test set are arranged around the perimeter of the drum and held in place by wooden wedges, the faces toward the inside forming a 10-sided polygon. The abrasive charge consists of about 200 lb of cast iron spheres, ten 3¾ in in diameter, and the remainder, about 133, 1⅞ in in diameter. These are

placed inside the rattler and the end of drum covered with a heavy wire screen. The test consists of the exposure of the blocks to the action of the spheres in the revolving drum for 3600 rev at a rate of about 30 rev per min. The loss in weight of the blocks has varied from 8 to 25%. The advantages which this method of testing is believed to have are as follows:

1. The concrete is subjected to a treatment which approximates that of service.
2. The test piece is of usual form and of sufficient size that representative concrete can be obtained.
3. The test pieces are convenient to make, store and handle, and require a relatively small amount of concrete.
4. The cost of the test is not excessive.
5. The machine used is found in numerous testing laboratories.
6. The wearing action takes place on the top or finished surface of the concrete. This makes it possible to study the effect of various surface treatments or finishes.
7. Several tests may be made at the same time, thus enabling more representative results to be obtained.
8. Tests may be made on sections of concrete cut from roads which have been in service.
9. Other paving materials such as brick, granite blocks etc may be tested in the same way as concrete."

Friction Tests of Cement-Concrete Pavements on Various Types of Subgrades (33). "The bases of concrete roads built in the past have been of varying character. Loam, clay, old macadam, gravel, sand and many other kinds of material support the concrete, and some offer more frictional resistance than others. In laying out the present series of tests, therefore, cognizance was taken of this fact and several different bases were used. Shallow ditches 6 in deep, 3 ft wide and 7 ft long were first dug in the soft clay soil of the Arlington Experimental Farm belonging to the U. S. Dept. of Agr. Filling material forming the subbase was then deposited under the supervision of a trained road engineer, tamped solidly and smoothed, or otherwise treated in readiness for the placing of the concrete. A 1 : 1½ : 3 mixture was used, machine mixed to a medium wet consistency, and the slabs cast were 2 ft wide by 6 ft long and 6 in thick. The various subbases prepared were as follows: (1) Clay, smooth top surface; (2) clay with cobblestones partly rolled in surface; (3) broken stone, ¾-in to dust, flat top surface; (4) concrete base, top surface, troweled smooth; (5) loam, smooth top surface; (6) sand, top surface smoothed and oiled with heavy flux oil; (7) clay, surface scored to make it uneven; (8) gravel, ¾-in to ¼-in, flat surface; (9) broken stone, 3-in; (10) concrete base, troweled surface, oiled with heavy flux oil; (11) sand, surface smooth; (12) clay, oiled with heavy flux oil.

"The first set of tests was made when the specimens were 1 month old. A frame made of a piece of ½-in round steel bent to surround the specimen was fastened to the pulling chain, which in turn was linked to a spring dynamometer. Force was applied by means of a light steel rail used as a long lever. Two men at the end of the lever were able to apply a constantly increasing force with great steadiness. The movements of the slab were read by means of a Berry strain gauge, and in this way the movements corresponding to known loads were obtained.

Table III.—Frictional Resistance of Concrete on Various Subbases

NOTE. Bases were somewhat damp but very firm. Weight of specimen, 870 lb.

Kind of Base	Movement	Force	Coefficient	Movement	Force	Coefficient	Movement	Force	Coefficient
Level clay	0.001	480	0.55	0.01	1130	1.30	0.05	1800	2.07
Uneven clay	0.001	500	0.57	0.01	1120	1.29	0.05	1800	2.07
Loam	0.001	300	0.34	0.01	1030	1.18	0.05	1800	2.07
Level sand	0.001	600	0.69	0.01	1080	1.24	0.05	1200	1.38
¾-in gravel	0.001	450	0.52	0.01	960	1.10	0.05	1100	1.26
¾-in broken stone	0.001	380	0.44	0.01	800	0.92	0.05	950	1.09
3-in broken stone	0.001	1060	1.84	0.01	1550	1.78	0.05	1900	2.18

"These results very clearly show that the friction varies considerably in the subbase, depending upon its character. The indications are that the friction can be greatly decreased if proper care is given to the preparation of the subbase. Every ridge or depression that is in the subbase surface before concrete is deposited, furnishes an additional grip for the concrete, thereby tending to elastically deform a larger amount of base material, and thus offering greater resistance to the sliding of the concrete.

"The formation of transverse cracks in concrete bases can readily be ascribed to direct tension due to frictional resistance at a time when the concrete is contracting, whether this is caused by decrease in temperature or by drying out of the moisture. The test results show that the coefficient of friction can readily vary from almost 0 to something over 2 or more, depending upon the movement of the concrete and the character of the subbase. The distance between transverse cracks is dependent upon the coefficient of friction, and the total force of friction must extend over this distance. Calling the coefficient of friction f, the distance between cracks d, the weight of the pavement per square foot w, we may write the equation: fwd = tensile strength of concrete per foot of width. Assuming the tensile strength of concrete to equal 200 lb per sq in, the pavement to be 6 in in thickness, the weight of 1 cu ft of concrete to be 150 lb, and the coefficient of friction to equal 0.5, this equation reduces to: $0.5 \times 75 \times D = 72$ sq in $\times 200$, or $D = 370$ ft. If the coefficient of friction equals 2, the distance between the cracks equals 90 ft."

10. Specifications for Aggregates

Fine and Coarse Aggregates. Report of Com. III, 1914 Nat. Conf. Concrete Road Building.

"**Fine Aggregates.** QUALITY. Fine aggregate shall consist of sand or screenings from hard, durable gravel, granite, trap, or other hard rock. It shall be clean, coarse, hard, free from dust, loam, vegetable, or other deleterious matter. Fine aggregate containing frost or lumps of frozen materials shall not be used.

"SAMPLES FOR TEST. Average samples of fine aggregate weighing not less than 10 lb shall be taken from the bank or pile and tested, before the acceptance of the material, for fineness and for tensile strength in mortar. Individual average samples shall be taken from each bank to be used, and new samples taken in case of a change in the character of any one bank. Receptacles for shipment to laboratory shall be such as to retain the natural moisture in the sand.

"FINENESS. The size of the fine aggregate shall be such that the grains pass when dry a screen having ¼-in openings. In the field a ⅜-in mesh or, in some cases, a ½-in mesh screen may be used for this separation. Not more than 10% of the grains below the ¼-in size shall pass a sieve having 50 meshes to the lin in, and not more more than 2% shall pass a screen having 100 meshes to the lin in. See (39) and (50d).

"TENSILE STRENGTH OF MORTAR. Mortars composed of 1 part Portland cement and 3 parts fine aggregate, by weight, when made in briquettes shall show a tensile strength at least equal to the strength of 1 : 3 mortar of the same consistency, made at the same time, and with the same cement and standard Ottawa sand. The sand shall not be dried before being made into briquettes, since this sometimes improves its quality, but correction shall be made for moisture when weighing the materials. Tensile tests may be made at ages of 72 hr, 7 days, and 28 days. At early periods the strength need not attain the full ratio of 100% to standard sand mortar, provided this is attained at a later period. In no case, however, shall sand be accepted for pavement work whose strength in 1 : 3 mortar at the age of 72 hr is not at least 80% of the strength of the standard sand mortar.

"SCREENING. If the sand does not fulfill the above requirements for fineness, it shall be washed or else screened when dry over a 10-mesh sieve placed at such an angle as to remove the particles finer than a 50-mesh sieve.

"WASHING. Fine particles may be removed by washing with a large volume of water in a box provided in the bottom with perforated pipes and arranged for the silt and water to flow off thru a trough from the top of the box and the sand to be drawn out from below.

"**Coarse Aggregate.** QUALITY. The coarse aggregate shall consist of clean, hard, durable granite, trap, conglomerate, gravel, or other hard rock, free from dust, loam, vegetable or other deleterious matter. In no case shall coarse aggregate be used which contains frost or lumps of frozen material. Coarse aggregate containing soft

particles shall be rejected. Coarse aggregate shall not contain a large proportion of flat or elongated particles.

"FINENESS. For one-course pavements, the size of the coarse aggregate shall be such as to pass an inclined or rotary screen having 1½-in circular openings and be retained on a similar screen having ⅜-in openings. For two-course pavements, the size of the coarse aggregate for the bottom course shall be such as to pass an inclined or rotary screen having 2-in openings and be retained on a similar screen having ⅜-in openings. For the wearing course in a two-course pavement, the coarse aggregate shall be of a size that will pass an inclined or rotary screen having ¾-in circular openings and be retained on a similar screen having ¼-in openings. This assumes a perfect bond between the first and second courses.

"Natural Mixed or Crushed Aggregates shall not be used as they come from the bank or crusher, but shall be screened and remixed in the proper proportions." See (20b) and (24d).

Am. Concrete Inst. and Am. Soc. Mun. Imp. Specifications for Fine and Coarse Aggregates are given in Art. 17.

Sand for Fine Aggregate for Cement-Concrete Base. Adopted by First Conference, 1917, State Highway Testing Engineers and Chemists.

"The sand shall consist of clean, hard, durable, uncoated particles, preferably silliceous, free from lumps of clay and all organic matter.

"Grading. It shall be well graded from coarse to fine and, when tested by means of laboratory screens and sieves, shall meet the following requirements:

Passing ¼-in screen	....	100%,
Passing 20-mesh and retained on 50-mesh sieve	.... % to	...%,
* Passing 50-mesh sieve	.... not more than	...%,

Not more than .....% by weight shall be removed by the elutriation test.

"Mortar Strength Test. When the sand is mixed with Portland cement in the proportion of 1 part of cement to 3 parts of sand, by weight, according to standard methods of making 1 : 3 mortar briquets, the resulting mortar at the age of 7 and 28 days shall have a tensile strength of at least....** percent of that developed in the same time by mortar of the same proportions and consistency, made of the same cement and Ottawa sand.

"Preliminary acceptance samples shall be subjected to both 7 and 28-day tests, and acceptance based thereupon. Samples tested during the progress of the work will be accepted on the basis of the 7-day test."

Sand for Fine Aggregate for Cement-Concrete Wearing Course. Same as above except for GRADING, the requirements for which are as follows:

"Grading. It shall be well graded from coarse to fine and, when tested by means of laboratory screens and sieves, shall meet the following requirements:

Passing ¼-in screen	....	100%,
Passing 20-mesh and retained on 50-mesh sieve	.... % to	...%,
†Total passing 50-mesh sieve	.... not more than	...%,
‡Passing 100-mesh sieve	.... not more than	...%,

Not more than ...% by weight shall be removed by the elutriation test."

NOTE: It is also recommended that the strength ratio, in the mortar strength test, be 100% instead of a minimum of 70% as in the previous specification.

Combinations of Dustless Screenings and Sand for Fine Aggregate for Cement-Concrete Wearing Course. Note: Same as for SAND FOR WEARING COURSE except as follows:

"The fine aggregate may be composed of a combination of dustless screenings and sand, but shall contain not more than ....¶ percent, by volume, of dustless screenings The dustless screenings shall consist of material obtained by crushing hard, durable

* "It is recommended that the amount passing the 50-mesh sieve be limited to 30%, or less, if practicable.

** "It is recommended that the minimum strength ratio for this purpose be 70% or greater, if possible under existing conditions; and that where sands giving a 70% strength ratio are not available, the proportion of cement be increased so as to give that percentage."

† "It is recommended that 25% be specified as the amount permitted to pass a 50-mesh sieve and in localities where practicable, that a smaller figure be used.

‡ "It is recommended that 5% be specified for material passing a 100-mesh sieve."

¶ The figure 50 is recommended.

rock or gravel, all of which when dry shall pass a revolving screen having circular openings ⅜-in in diameter. They shall be free from lumps or crusts of hardened material. The sand shall consist of clean, hard, durable, uncoated particles, preferably siliceous, well graded from coarse to fine, and free from lumps of clay and all organic matter.

"**Physical Properties of Dustless Screenings.** If the dustless screenings are produced from rock, the rock shall meet the following requirement:

Percent of wear.......................... not more than ...%,
or French coefficient.......................... not less than ......

"**Grading of Dustless Screenings.** The dustless screenings shall be well graded from coarse to fine, and, when tested by means of laboratory screens and sieves, shall meet the following requirements:

Passing ¼-in screen.......................... not less than ...%,
Passing 20-mesh and retained on 50-mesh sieve.......... % to ...%,
Passing 100-mesh sieve...................... not more than 5%."

Stone or Gravel Screenings for Fine Aggregate for Cement-Concrete Base. Adopted by the First Conference, 1917, State Highway Testing Engineers and Chemists.

"The screenings shall consist of material obtained by crushing hard, durable rock or gravel, all of which shall pass a revolving screen having circular openings ⅜ in in diameter. They shall be free from lumps of clay and at the time of use from lumps or crusts of hardened material.

"**Physical Properties.** If the screenings are produced from rock, the rock shall meet the following requirement:

Percent of wear.......................... not more than ....%,
or French coefficient.......................... not less than ......

"**Grading.** The screenings shall be well graded from coarse to fine and, when tested by means of laboratory screens and sieves, shall meet the following requirements:

Passing ¼-in screen.......................... not less than ...%,
Passing 20-mesh and retained on 50-mesh sieve.......... % to ...%,
Passing 100-mesh sieve...................... not more than ...%.

"**Mortar Strength Tests.** When that portion of the screenings, which passes a ¼-in laboratory screen, is mixed with Portland cement in the proportions of 1 part of cement to 3 parts of screenings, by weight, according to standard methods of making 1 : 3 mortar briquets, the resulting mortar at the age of 7 and 28 days shall have tensile strength of at least ...* percent of the strength developed in the same time by mortar of the same proportions made of the same cement and Ottawa sand.

"Preliminary acceptance samples shall be subjected to both 7 and 28-day tests and acceptance based thereupon. Samples tested during the progress of the work will be accepted on the basis of the 7-day test."

Broken Stone or Gravel for Coarse Aggregate for Cement-Concrete Base. Adopted by First Conference, 1917, State Highway Testing Engineers and Chemists.

"The broken stone or gravel aggregate shall consist of clean, hard, tough, durable rock. It shall contain no vegetable or other deleterious matter, and shall be free from soft, thin, elongated or laminated pieces.

"**Grading.** The broken stone or gravel shall be graded from coarse to fine and when tested by means of laboratory screens shall meet the following requirements:

Passing ... in screen.................................. 100%,
Passing ... in screen...................... not more than ...%."

Broken Stone for Coarse Aggregate for Cement-Concrete Wearing Course. Same as for BROKEN STONE FOR BASE, except as follows:

"**Physical Properties.** The stone shall meet the following requirements:

Percent of wear.......................... not more than ...%,
or French coefficient...................... not less than .....

"**Grading.** The broken stone, when tested by means of laboratory screens, shall meet the following requirements:

Passing ... in screen.................................. 100%,
Passing ... in screen and retained on ... in screen...... % to ...%,
Passing ... in screen...................... not more than ...%."

*It is recommended that the minimum strength ratio be 90% for this purpose.

CONSTRUCTION

11. Equipment and Construction Organizations

The Equipment necessary for concrete road construction will depend largely on local conditions. For an admirably comprehensive list of the field and office appliances used in constructing by force account twelve miles of concrete roadway in one working season see (26b).

Examples of Concreting Gang Organization (50r) for road work are given in the following examples.

" **Pennsylvania. Easton-Bethlehem Model Road.** The best results were obtained with a gang organization as follows:

Gang	Cost per Day
1 foreman at $3	$3.00
1 mixer operator at $3	3.00
1 fireman at $2.50	2.50
2 templet men at $2	4.00
3 men spreading at $2	6.00
2 men floating at $2	4.00
1 man finishing at $2	2.00
2 men on forms at $2	4.00
1 man changing chute at $2	2.00
2 men handling cement at $1.75	3.50
7 men on wheelbarrows at $1.75	12.25
7 men shoveling at $1.75	12.25
1 utility man at $1.75	1.75
1 waterboy at $1.50	1.50
32 men in total gang,	$61.75

Laying a slab 7 in thick and holding the material in the drum for a 90-sec mix, this gang averaged 525 sq yd per day at a cost of approximately 11.7 cents per square yard. A No. 16 Koehring paving mixer, with boom and bucket delivery, was used.

" **Illinois.** The data given are based on experience on 25 to 30 jobs of state aid road work representing approximately 500 000 sq yd of pavement. Assuming excavation complete and all material delivered on the work and that the subgrade is in average condition, the following crew is considered to be most efficient under average conditions on work similar to state aid road work in Illinois.

General	Number
Superintendent	1
Foreman	1
Front End of Mixer	
Wheeling sand	2
Wheeling stone	4
Extra shovelers	2
Bundling cement sacks	1
Handling cement	2
Trimming subgrade	1 or 2
Rear End of Mixer	
Shovelers	3 or 4
Finisher	1
Curing concrete	2
On Mixer	
Engineer	1
Fireman	1
Forms, Setters	2
Water, Pumpman	1
Miscellaneous	
Watchman	1
Waterboy	1
Total	27 or 29

The gang is for a 2-bag batch mixer, and with this machine its average daily output of 18 ft wide and 7 in thick pavement is about 800 sq yd, working day 9 hr, mixing time per batch, 35 sec. The average cost of mixing and placing concrete and of setting forms and joints is 10 to 12 cents per sq yd.

" Wisconsin, Milwaukee County Roads. An efficient gang organization for conditions prevailing in Milwaukee County has been found to be about as follows:

Gang	Cost per Day
1 foreman at $5	$ 5.00
1 timekeeper at $5	5.00
1 engineer at $5	5.00
1 fireman at $2.50	2.50
1 pumpman at $2.50	2.50
1 form setter at $2.50	2.50
1 finisher at $3	3.00
2 strike-off men at $2.50	5.00
2 puddlers at $2.50	5.00
2 cement handlers at $2.50	5.00
1 boy bundling sacks at $1.50	1.50
1 waterboy at $1	1.00
6 sand laborers at $2	12.00
12 stone laborers at $2	24.00
1 man removing forms at $2	2.00
2 men covering concrete at $2	4.00
1 man sprinkling at $2	2.00
1 man trimming subgrade at $2	2.00
38 men total	$89.00

"The particular road on which this gang worked contained 17 280 sq yd, was 18 ft wide and averaged 7 in in thickness. The mix was 1 : 2 : 3½, 2 bags of cement being used to a batch, and 11 cu ft of aggregate. Protected joints were placed every 50 ft. During this period, the maximum output for one day was 1000 sq yd and the minimum 264 sq yd. The average output was 665 sq yd per day or 332½ lin ft per day. The actual labor cost for mixing and placing was $0.1396 per sq yd, which included labor incurred in supplying water covering and sprinkling concrete and also a watchman during the construction period. The cost to the contractor for lost time, moving plant to and from the job, the laying of pipe, etc, amounted to $0.0201, giving a total cost per sq yd for labor of $0.1597."

12. Mixed Cement-Concrete Pavements

One-Course Work is simply the construction of the entire concrete layer from the subgrade up to the finished surface continuously and in consecutive areas of pavement. The placed concrete, such as the Hassam pavement, before referred to, constructed as one-course work because the grouting is done entirely from the top of the aggregate when rolled, even tho the aggregate itself may be laid in two or more layers. With mixed concrete, the deposition of the entire concrete layer in one thickness would be one-course work. One-course work seems to be growing somewhat in favor, altho the difficulties of properly tamping and compacting a layer of the usual thickness of one-course work are apparently greater, than in the case of the two-course work where the layers are of less thickness.

Two-Course Work consists in placing the concrete pavement in two layers, generally known as the bottom course and the top course respectively. Frequently the bottom layer is of coarser aggregate than the top layer and it often is of a leaner mixture of cement for the sake of economy. In these respects, it is similar to the ordinary side walk or foot-way construction when concrete is used. The difficulties with two-course work seem to be

mainly those of securing a proper bond between the lower and the upper courses. Generally in two-course work, especially where different materials and proportions are used in the two courses, the bottom course is laid for some distance ahead of the upper course, and then the upper course is run. A certain amount of setting in the lower course unavoidably takes place before the placing of the upper course begins, and a seam frequently appears to exist between the two courses which results in weakening the strength of the upper thickness, just as a 2-in plank laid on another will not support as much of a load with the same deflection as one plank 4 in in thickness. Further with a great deal of two-course work, it has been noticed that there is a tendency at the expansion joints for the upper course of one of the areas to separate from its lower course and override the upper course of the adjoining area, especially where expansive movement of the concrete is considerable. This is of common notice in many side walk pavements of concrete. It is possible with two-course work to secure a denser wearing surface of the pavement with no greater expenditure for cement than can be had with one-course work, and, especially where the concrete pavement is to be directly subjected to traffic, a high degree of density in the wearing surface is desirable. On the other hand, with equal proportions of cement, the one-course work is probably stronger under heavy loads, and over soil or other foundations of weak supporting power than the two-course work, and this is an important consideration where the total thickness of the concrete layer is near the minimum allowable.

The Report of Com. XI, 1914 Nat. Conf. Concrete Road Building included the following recommendations:

Depositing Concrete. "Just before placing concrete, the subgrade should be well sprinkled so that it will not absorb moisture from the concrete, and should be checked by the engineer or inspector to make sure that the required thickness of concrete can be placed. Probably the most satisfactory method of depositing the mixed concrete in position on the subgrade is by means of a bottom dump bucket running on a swinging boom from the mixer. The boom can be swung over any position on the subgrade, and the bucket can be run out and dumped at any point along the boom. Such equipment does not depend for economic operation upon consistency, and the concrete can be easily handled and deposited at any place on the subgrade, necessitating but little handling with shovels. When concrete is placed by means of the open trough, care must be exercised to see that it is not mixed too wet as this method of distribution depends for economic operation very much upon the consistency of the concrete. An open trough is necessarily much shorter than a boom and is more limited in action, which requires that the mixer be moved ahead more often, also that more of the concrete after being deposited on the subgrade be handled with shovels. When a batch mixer, not having a boom and bucket or open trough, is used, the concrete should be handled in wheelbarrows or hand carts wheeled on suitable runways. Placing concrete by means of horse carts should not be permitted as they cut up the subgrade badly, and to get the concrete into final position requires a maximum amount of shoveling. Whatever the method of conveying and placing, the concrete should be deposited upon the subgrade to the required depth and for the entire width of pavement in as nearly one operation as practicable so as to reduce handling to a minimum. If it is necessary to handle a large amount of material with the strike-board it will ride the concrete and thus produce a wavy, uneven surface.

"**Use of Strike-Board.** The excess of coarse material that accumulates in front of the strike-board should be uniformly distributed over the surface of the pavement and not left in narrow strips across the section, or placed along transverse expansion joints. An ordinary garden rake will be found useful in distributing the material that accumulates in front of the strike-board. When the strike-board is within 2 ft of an expansion joint, the excess material that has accumulated in front of it should be removed with a shovel and deposited on the subgrade in the next section. Special care should be taken to place good dense concrete along expansion joints, and all in-

equalities at the joints, including any small holes left after the removal of the installing device, should be filled with a mortar composed of one part cement and not more than two parts fine aggregate. The men handling the strike-board should follow closely behind those placing the concrete, for keeping up with the strike-board will materially assist those placing concrete in depositing the required amount of material. The placing of concrete should be a continuous operation, and stops should be made only at expansion joints. In case the mixer breaks down concrete should be mixed by hand to complete the section, or an expansion joint should be placed at the point of stopping work. Any concrete in excess of that needed to complete the section, when work is discontinued, should be spread out in a thin layer, not exceeding 2 in in thickness, over the subgrade in the next section and not piled up along the expansion joint. In striking off a pavement 16 ft or less in width, where the concrete has been properly placed, two men should be able to handle the strike-board, but for wider pavements the services of a third man will be required to assist in pulling the board forward by means of a drag line fastened at its center. The strike-board should always be worked forward about perpendicular to the axis of the roadway, and as it is moved ahead should be sawed back and forth across the road. To produce the desired effect will require that the strike-board be passed over the surface of the concrete two or more times. Tho it will be necessary for the workmen to get into the concrete some after it is deposited on the sub-base, it is desirable that all unnecessary walking in and wading thru the concrete be avoided, and under no circumstances should any workmen step upon the concrete after it is first struck off." See (50j).

"**Description of Strike-Board.** The strike-board should be cut to conform to the crown of the finished surface of the pavement and should be of sufficient strength and stiffness to show no deflection at the center when supported at the ends, nor a material bowing out of alignment when in use. It should be about 2 ft longer than the width of the road, protected on the bottom edge with a metal facing and provided at each end with suitable handles. For roads up to 12 ft in width two 2 by 6-in planks, dressed on one side and both edges, spiked together, make a good strike-board, and for roads 12 to 20 ft in width two 3 by 8-in or a 2 by 10-in and a 3 by 10-in, spiked together, will be found satisfactory. Two planks, well spiked together, make a better strike-board and one less likely to warp out of shape than a single piece. The strike-board should not be so heavy that it cannot be easily handled by two men, and to reduce weight and increase stiffness, it is advisable for work over 20 ft in width to use a strike-board composed of boards 2 or 3 in thick, stiffened by trussing, rather than obtain the required stiffness by the use of heavier timbers."

The Use of a Belt in Surfacing Concrete Pavements. (19a) "Two belts were secured; one 3-ply 8-in canvas belt and one 5-ply 10-in belt, both having a composition rubber covering. The concrete was mixed at such consistency that when deposited in a pile it would tend to flatten but would not run at the edges. The concrete was struck off in the usual manner and after the surplus water disappeared from the surface of the concrete, the 8-in belt was dragged back and forth over the pavement with practically the same motion as used for the strike-board. Just prior to the concrete taking its initial set the pavement is gone over a second time with the belt. This second floating grinds down all the ridges left after the first floating. The second floating leaves a gritty, granular mortar surface entirely free from ridges, flat spots or pockets. It was found that better results could be secured by the use of a 10-in belt for the second floating because of its greater weight, but if the heavier belt was used for the first floating, it had a tendency to flatten the crown in the soft concrete and to dig into the surface. In Kane County the contractor is placing from 600 to 800 sq yd of 18-ft concrete pavement per day and has no finisher on the pay roll. The strike-board men handle the belt and do the edging. Where armored joints are used it is necessary to do a small amount of hand floating around the joint, but this is done by the men who place the joints. This construction feature appeals to the contractor as it saves him money and the worry of keeping a good finisher on the job; and it appeals to the engineer because of the superior surface and the fact that its operation is nearly foolproof."

Rolling the Concrete after its placing has been referred to. Theoretically such rolling is desirable for securing the proper compaction of the mass, for securing greater homogeneity in and evenness of surface, and for securing in the surface such disposition of the larger particles of aggregate

such as broken stone, as will result in their closely interlocking by their angles and their presentation to wear of a flat face rather than of an edge or point. Practical difficulties often exist in the way of rolling the wet mixture without interfering disadvantageously with the setting process. Rolling has, however, been done on mixed concrete with much success. For a description of means and methods see (16), and VIBRATED CONCRETE, Art. 17.

Curing the concrete properly is a most important detail of construction. Some means must be had for retaining sufficient moisture in the mass and adjacent to it sufficient to prevent, as far as practicable, while the setting is taking place, the formation of cracks or a loss of strength in the concrete. One fairly satisfactory method has been to allow the finished concrete to harden superficially, enough to prevent its being damaged by the process, and then to cover it with several inches of sand or earth, which latter is thereafter kept constantly wet by being sprinkled. Another means has been to build low earth dams along and across the concrete roadway impounding a few inches of water within the dams and over the concrete. Wet canvas or straw coverings have also been used. See (32) and (50i).

18. Expansion-Contraction Joints

In uncarpeted concrete pavements, it may be necessary to provide opportunities in the form of prepared joints whereby the movement of the concrete slab thru expansion and contraction under varying climatic conditions can be taken up with the minimum of injury to the slab itself. Such joints are ordinarily termed expansion joints, but as a matter of fact, the better name for them would be contraction joints. It has been sufficiently demonstrated that the movement in the concrete slab due to varying degrees of moistness of the slab is far greater and appreciable than that due to varying degrees of temperature of the slab. Changes in temperature produce some movement in the slab but the movement so produced is so slight that it is almost negligible, except in cases of the longest slabs. On the other hand, the movement in the slab occurring between the condition when it is most nearly saturated with water and the condition when it is freest from water is relatively large, and it is this movement for which provision must be made in order to protect the slab itself. Concrete being laid in a saturated condition must at that period occupy its greatest area of the road. As it sets and dries out, it contracts and cracks tend to form.

The Minor Superficial Cracks thus formed are frequently termed hair cracks, and generally affect only the surface. They are of almost negligible importance, outside of considerations of appearance, in connection with the use of concrete for pavements. Their reduction to the minimum is dependent upon the composition, workmanship, and the ultimate density and strength of the concrete itself. In the case of large slabs, the shrinking movement due to drying may reach such proportions as to produce separation in the slab itself between portions of the slab unable, for one reason or another, to conform further to the shrinking movement. See (28b).

The Difficulties of the Construction of Joints come mainly from the increase in cost in providing them, and the obstacles at present existing in the way of securing a proper joint filler under any particular condition. Some form of bituminous filler is the usual material used and various advantages are claimed for the different ones on the market. Characteristerics desirable in the bituminous filler are sufficient adhesion to prevent its separation from the concrete adjoining, sufficient cohesion to prevent separation in the bituminous filler itself, sufficient resistance to heat to prevent

its flowing out of the joint in the hottest weather, sufficient resiliency to prevent its being broken out of the joint by the shocks of traffic in the coldest weather, and such durability of these qualities as will give a reasonable and satisfactory life under use.

The Provision of Expansion Joints in an uncarpeted concrete pavement, or in a concrete pavement under which a carpet of less than ½ in thickness is expected to be maintained is usually made. In the uncarpeted roadway, they may be made from 25 to 100 ft apart, the distance between them being dependent upon local conditions, and should extend across the roadway the full depth of the slab. In the thinly carpeted road, they may safely be at greater intervals or omitted altogether. They may be either at right angles to the axis of the road, or at a different angle. The angle of 45° with the axis of the road has been recommended, especially from the greater ease of passage over the joints, tho the length and cost of the latter is evidently increased by the adoption of this angle. On curves it is customary to make them radial. The width of the joints in any case must depend upon local conditions as well as upon the frequency determined upon. The Hassam pavement does not seem to require for its protection contraction joints to the extent required by other concrete slabs. See (54).

The Report of Com. II, 1914 Nat. Conf. Concrete Road Building (50c) contained the following conclusions:

"**The Expansion Joint Should Fulfill the Following Conditions:**

1. It should be located at the proper spacing, experience points to a distance of 25 to 30 ft when the pavement is not reinforced.
2. It should be designed of sufficient thickness and depth to withstand the traffic.
3. Metal should be hard enough to withstand abrasion but should not be brittle.
4. The expansion joint protector should be simply installed.
5. It should provide a strong bond with the road slab.
6. The filler between the protectors should be plastic to permit expansion and contraction, and keep out grit and water. Both plastic asphalt and tar felt paper are used with satisfaction.
7. The protector should be as inexpensive as consistent with good service. The subject of expansion joints for concrete pavements resolves itself into three divisions, namely, Location, Type and Maintenance.

"**Maintenance of Joints.** Expansion joints should be kept filled to the level of the pavement surface so that there will not result an impact when wheels cross the joint. If the joint is not kept filled, grit will accumulate and in time the joint will be filled with non-elastic material. Even a joint which has been kept filled will in time become jammed with grit."

In this connection, the report of Com. I (50a) on the "Contraction and Expansion of Concrete Roads" is very full and extremely valuable for study. See (30) and (69a).

Pennsylvania Practice (63). "Joints, ¼ in wide, are provided at intervals of from 36 to 40 ft. These are filled with a prepared bituminous material, ¼ in thick and 9 in wide, placed in accordance with the standard practice. The concrete on either side of the joint is finished with a split float, which gives a surface of even height on both sides of the joint and overcomes to a great extent the so prevalent rough riding joints. The edges of the joints are then rounded with a $^3/_{16}$-in edger to prevent the spalling or breaking of the edges. The bituminous joint material is trimmed off about 1 in above the finished surface, which permits traffic to beat down the projecting filler, thus forming a protection to the edges. The sides of the slab are then rounded with a ¼-in edging tool, which not only adds to the appearance of the work, but serves also to protect the sides and prevents chipping by traffic turning on and off the road."

Omission of Joints. The tendency in practice seems to be toward the omission of prepared joints and the reliance upon other means, such as reducing the movements and strains in the slab by securing greater uniformity and density, for meeting the demands of conditions causing contraction and expansion. The California practice has been to omit the provision of expansion joints, see (31). See also (21), (50b) and (50c).

14. Reinforced Cement-Concrete Pavements

The effort has been made to increase the strength of concrete slabs for road pavements, and also their power of resistance to expansion and contraction strains by the insertion of metal reinforcement in the body of the concrete. The usual method of so doing is to have the reinforcement in the shape of wire netting, or some of the special forms like the expanded metal meshing, and to place this reinforcement between the bottom and top courses of the pavement. Where used with one-course work, such as the Hassam pavement, a layer of stone is usually spread and rolled, then the netting placed on this surface and the final layer of stone spread over the netting and rolled. Some additional strength is undoubtedly given the concrete slab by the presence of the reinforcement. Its resistance to deflection under a load is relatively only slightly increased because of the tendency of the reinforcement to divide the slab with a seam into two layers, between which resistance to shear may be low, while the increase in bending moment can only be figured by the additional strength given from the reinforcement to the beam having the depth only from the upper surface to the reinforcement, instead of the whole depth of the concrete slab. The reinforcement undoubtedly adds considerable to the tensile strength of the slab and should permit the location of the contraction joints considerably further apart than in the cases of unreinforced slabs. See (62).

The Report of Com. V, 1914 Nat. Conf. Concrete Road Building (50f) included the following conclusions:

"Since concrete has little tensile strength, it is inelastic and cracks may develop from the following causes: (1) Changes in temperature; (2) variation in the percentage of moisture in the concrete; (3) defective foundation; (4) improper drainage; (5) insufficient thickness in slab to carry the traffic; (6) faulty construction.

"It is necessary, therefore, in a pavement properly designed and constructed, to minimize the cracks resulting from the above causes by imbedding a reinforcement in the concrete which will so distribute the tensile stresses as to prevent formation of larger cracks.

1. Reinforcement for Temperature Changes. The effect of an increase of temperature is to increase the length or expand the concrete pavement and a decrease in temperature is to decrease or shorten the pavement. In the latter case, assuming that there is no reinforcement, cracks will form at more or less regular intervals. These cracks will occur at right angles to the direction of the line of the roadway at intervals of 25 or 50 ft. Since concrete and steel have practically the same coefficient of expansion, namely, 0.0000055, the two materials will expand or contract equally under temperature changes, but the presence of the steel prevents the entire effect from being localized at one point and distributes the stress over a considerable space, thereby preventing any large cracks. The common practice is to provide joints in concrete pavements that are not reinforced at intervals of from 25 to 50 ft. Thru the use of reinforcement the spacing of these joints may be very materially increased and it is possible to so reinforce a concrete pavement as to render joints either wholly unnecessary or at extremely long intervals. By properly reinforcing the roadway, the thickness may within limits be decreased thereby increasing the serviceability of the roadway and decreasing the cost.

2. Variation in the Percentage of Moisture in the Concrete. Experiments seem to indicate that concrete expands when thoroly wetted and shrinks when thoroly dried out, and that the change of length due to this cause is about 0.005 per unit of length. Experiments seem also to show that expansion and contraction, due to the variable content of moisture which results from extreme wet or dry weather, produces cracks in the concrete, unless the pavement is sufficiently reinforced to distribute these stresses in the manner described under reinforcement for temperature changes. Further proof is desirable, however, before this fact is accepted, and further experiments are needed to show the effect of density and mass on the percent of moisture in concrete. It seems likely that a very dense mass of concrete of some thickness will only be superficially affected and the mass will not be materially affected.

3. Defective Foundation. Concrete pavements laid on a subgrade which contains fills or other soft places which are liable to settle, thus leaving the concrete pavement without proper support, will result in cracks unless the pavement be sufficiently reinforced to distribute the load over a larger area, thereby bridging over these soft places where there has been settlement in the subgrade.

4. Insufficient Thickness of Slab to Carry the Traffic. Where the traffic on the road is very heavy it frequently happens that the concrete unreinforced is insufficient in thickness to support this load, especially if the subgrade is not of suitable character, and both longitudinal and transverse cracks are the result. Settlement in the foundation under heavy traffic will produce objectionable longitudinal cracks. The introduction of reinforcement in the pavement distributes the load and thereby prevents the formation of these cracks.

5. Faulty Construction. These same cracks and imperfections appear when faulty construction occurs, which is generally the result of improper design or supervision, or both.

"The percentage of reinforcement required in a concrete roadway will depend on the nature of the traffic, the conditions in the subgrade and the range of temperature and the variation in percentage of moisture. Your Committee, therefore, is unable to prescribe the exact amount of reinforcement required since it will vary with each road. In general, however, the reinforcement should be about 0.1% per foot of width."

The Report of Com. IX, 1916 Nat. Conf. Concrete Road Building (50f) opened with the following statements:

"Your Committee, in considering the reinforcement of concrete roads, find little data available and no well defined practice. Many highway engineers use the recommendations of the 1914 Nat. Conf. Concrete Road Building and the standard specifications of the Am. Concrete Inst.. It is only recently that reinforcement has been used to any great extent, and the interval is too short for the accumulation of the data necessary to standardize practice."

It included among many others of interest in this connection, the following paragraphs: "While not directly within its province, your committee believes that the number and the character of the joints have a vital bearing on the life of a concrete road. It further believes that joints may be greatly decreased or practically eliminated by proper reinforcement. All joints are objectionable and many are a menace to the life of the concrete road."

The Committee recommended that "all concrete roads shall be reinforced", but the Conference itself in its "Recommended Practice" simply stated on this point that "The use of reinforcement in concrete pavements is increasing."

Rods Hold Settling Concrete Pavement Together (19b). "Twelfth St., Cook County, Ill., east of Hillside, presents a striking example of the settlement of a rigid pavement laid on a yielding subgrade. At this point the road extends thru a slough for 600 ft, and tho the maximum settlement at the time the last levels were taken was 1.74 ft, it is still in good condition. While a considerable number of small transverse cracks have developed, no longitudinal or diagonal cracks have appeared. The longitudinal reinforcement has kept the cracks from becoming large, and if these are given ordinary maintenance, the utility of the road will not be seriously impaired.

Table IV.—Settlement of Center of Road in Inches

Station	Aug. 18, 1915 After 43 Days	Mar. 9, 1916 After 8 Months	Nov. 17, 1916 After 16 Months
155	0.02	0.00	0.01
156	0.00	0.00	0.01
157	0.24	0.58	0.90
158	0.32	0.73	1.09
159	0.37	0.79	1.11
160	0.60	1.29	1.74
161	0.49	1.14	1.56
161 + 38	0.08	0.49	0.81

Specification for Steel Reinforcing Rods. Adopted by First Conference, 1917, State Highway Testing Engineers and Chemists.

"Rods shall be (insert form selected)* and (insert method of manufacture desired)** and shall conform to the following chemical and physical requirements. Twisted bars shall be twisted with one complete twist in a length not over 12 times the thickness of the bar.

"**Chemical Properties.***** Rods shall meet the following chemical requirements:

Phosphorus	Bessemer	not more than x %
	Open-hearth	not more than x %

"**Physical Properties.** Rods shall meet the following requirements for physical properties:

Tension Tests:	
Tensile strength	not less than x lb per sq in
Yield point	not less than x lb per sq in
Elongation in 8 in	not less than x %
Cold bend test without cracking:	
Thickness or diameter ¾ in	x°.
Thickness or diameter ¾ in or over	x°.

"**Modifications in Elongation.** For plain and deformed bars over ¾ in in thickness or diameter, a deduction of 1 from the percentages of elongation specified in the foregoing table shall be made for each increase of 1/8 in in the thickness or diameter above ¾ in. For plain and deformed bars under 7/16 in in thickness or diameter, a deduction of 1 from the percentage of elongation specified in the foregoing table shall be made for each decrease of 1/16 in in thickness or diameter below 7/16 in.

"**Weight.** The weight of any lot of bars shall not vary more than 5% from the theoretical weight of that lot.

"**Storage.** Steel rods shall be so stored as to prevent the formation of rust scales and when used on the work they shall be free from dust, dirt, loose rust, paint, oil or grease."

15. Specifications for Mixed Cement-Concrete Pavements

Fundamental Principles Adopted by the 1916 Nat. Conf. Concrete Road Building (50a), as representing good practice in the construction of concrete pavements:

"**Brief Summary of Fundamental Principles.** The salient features of the practice recommended by the Conference are:

1. Drainage of the road-bed is vital.
2. Subgrade must be of uniform density and should be compacted.
3. Aggregates must be clean, hard and tough.
4. Fine aggregate, sand, should be coarse and well graded.
5. A rich mixture must be used.
6. Materials must be accurately proportioned.
7. Mixing must be most thoro.
8. Sloppy concrete must not be used.
9. In general, the use of reinforcement is justifiable.
10. Inspection must be intelligent and thoro.
11. Concrete must be protected from rapid drying.
12. Pavements must not be opened to traffic too soon.

"The details of recommended practice are as follows:

"**Materials.** PORTLAND CEMENT shall meet the requirements of the Standard Specifications for Portland Cement of the Am. Soc. Test. Mat. and tests should be made in accordance with the methods of testing outlined by the Am. Soc. C. E. See (69c).

---

*Plain, deformed, hot or cold twisted, as may be desired.

**Rolled from new billets made by Bessemer or open-hearth process or rolled from standard section Tee rails, as may be specified.

***To be applied only to rods rolled from billets.

x The values given in American Society for Testing Materials Standards, 1916, Serial Designation A15–14, for the particular kind of material desired, are recommended for insertion in this table.

"AGGREGATES. The selection of proper aggregates for concrete pavement construction is of utmost importance. Clean, hard, well graded materials are absolutely essential to success. For this reason samples of the materials proposed for use should be submitted to the engineer for approval before orders are placed. These samples should be carefully inspected; and, if possible, laboratory tests be made upon them to determine their suitability. If laboratory tests on shipments cannot be made, field tests can be used to furnish a general indication of quality. The different aggregates should be kept clean, and separate until used. Aggregates to be used in the wearing course of two-course pavements should never be placed on the subgrade but on planks, unless some other means is provided to keep them free from dirt. If aggregates are placed directly on the subgrade, care should be used by the shovelers to avoid getting clay or earth, shoveled from the subgrade, into the mix. Aggregates should not only be clean when they are delivered on the job, but clean when placed in the mixer.

"WATER SUPPLY is a most important factor and is frequently overlooked by the engineer and contractor. A large supply of water is necessary for (1) sprinkling the subgrade; (2) mixing the concrete; and (3) keeping the concrete moist during early stages of hardening. For the last purpose 25 to 30 gal per sq yd of pavement will be required during the summer months. Unless sprinkling is thoro the wearing qualities of the pavement will not be all they should be.

"The use of REINFORCEMENT in concrete pavements is increasing. A coating of light rust will not be detrimental to satisfactory results but care should be exercised that no excessive rust, paint or other coatings are present to interfere with proper bond. Care should also be exercised to see that the reinforcement is so stored prior to use, that it is not coated with mud or clay when placed in the pavement. Reinforcement left on a job when the contract is not complete at the end of the season should be collected and stored so that it will be protected from the elements. Occasionally tensile and bending tests should be made to see that the requirements of the specifications are fulfilled.

"JOINT FILLER should preferably be of a single thickness. Transverse joint filler should be cut to the crown of the pavement by the manufacturer, when metal plates are used. A type of joint filler which will iron out readily under traffic is preferable for use in unprotected joints. A joint filler which will not bend easily when concrete is deposited against it is to be preferred.

"METAL JOINT-PROTECTION PLATES should be properly bundled and wired by the manufacturer so that they will arrive on the work in good condition, free from warp. Protection plates up to 20 ft shall be shipped in single lengths. The exact length required should be provided so that the contractor will not find it necessary to cut plates. In cutting plates for length, spacing between eccentrics on the installation bar should be considered to avoid interference with anchorage lugs on plates. Particular care should be used by the manufacturer in crowning the installing bar, to avoid the necessity of duplication of work by the contractor.

"The Drainage of the road-bed is of vital importance. If the subgrade is not well drained, there is danger of unequal settlement or frost action, which will cause cracks. The method of drainage to be used will depend upon local conditions. For roads, proper drainage may be secured thru lateral ditches. For streets, as well as roads, tile drains may be used. These should be laid on each side of the roadway, or may be laid on one side only, with cross-drains leading thereto at a suitable depth, depending on the width of the pavement. Drainage trenches, if placed under the subgrade, should be completed before final rolling.

"Grading. When roadways are constructed over fills, extreme care should be observed to insure the use of proper materials in layers of such thickness that the materials may be thoroly compacted so that when the fill is completed there will be a minimum of settlement. In general, fills shall be made in thin layers, the thickness depending on the character of material to be used in making the fill. The fill should be allowed to stand for as long a time as possible, to give it an opportunity to settle thoroly before the pavement is placed thereon. Deep fills should be allowed to settle thru one winter wherever such procedure is possible. Puddling will be found advantageous in compacting deep fills. Wetting and rolling shall be performed when making a fill in order to secure thoro compactness. Fills should never be made with frozen materials, nor with lumps greater than 6 in in their greatest dimension.

"Subgrade. The fundamental requirement of the subgrade is that it should be of uniform density so that it will not settle unevenly, thus causing cracks in the surface

of the pavement. No part of the work is more deserving of intelligent care and pains-taking labor than the preparation of the subgrade. The slight additional cost necessary to insure good results is abundantly justifiable. When the pavement is constructed on virgin soil, care should be taken to remove all soft spots so as to insure a uniform density; and if constructed on an old road-bed, even greater care must be taken to secure uniform density, as the subgrade is likely to be more compact in the center than at the sides. An old road-bed should be scarified, reshaped and rolled. The subgrade adjacent to the curb should be hand tamped.

"**Forms.** Metal side forms of sufficient strength to withstand the necessary hard usage are preferred. When wooden forms are used they should be of 2-in stock, at least, and capped with a 2-in angle iron, and so constructed that adjacent sections can be lapped. Forms should have a width not less than the thickness of the pavement at the sides. Particular care should be exercised to see that the top edge of forms is clean so as to avoid unevenness in the finished pavement. If forms are warped or stakes not properly placed, a poor alignment of the edge of the concrete slab will result. See (70).

"**Pavement Section.** The THICKNESS of a concrete pavement is controlled by many factors, each of which should be given consideration. In view of the increasing use of the heavy motor truck and bus, it seems unwise to build pavements with a thickness of less than 6 in at any point. In general, pavements should be thicker at the center than at the sides. Alleys with an inverted crown, and narrow one-slope roads, should have a uniform thickness. Wherever the thickness can be increased without excessive cost, to secure a flat subgrade, or one nearly flat, such increase is advisable.

"The desirable WIDTH for a single-track road is 10 ft. The desirable width of double-track roads is 18 ft. The total width of the roadway should be not less than 20 ft for single-track roads and not less than 26 ft for double-track roads.

"The CROWN of pavements should be not less than 1/100 nor more than 1/50 of the total width. Except in unusual cases, 1/100 will be considered satisfactory for alley pavements. For city streets an average crown of 1/75 will generally be found sufficient, and should not be reduced, except on grades.

"**Joints.** TRANSVERSE JOINTS should be placed across the pavement perpendicular to the center line about 50 ft apart. There seems to be a tendency to widen the distance between joints. Joints should extend entirely thru the pavement, as well as thru the curb if integral curbs are used. Joints should be constructed perpendicular to the surface of the pavement to avoid the possibility of one slab rising above the other.

"LONGITUDINAL JOINT FILLER should be staked or otherwise securely held against the curb. Joint material should also be placed around manholes, catch basins, etc.

"PROTECTED JOINTS. The tendency of present practice is toward the omission of metal protection plates for joints. It is possible that the value of metal protection plates is dependent somewhat on the character of aggregate used, and it is considered that they are more essential in street pavements than in country highways.

"PLATES for protected joints should be wired together with the joint filler in place and securely held in the installing bars. When short sections of joint filler are used they should likewise be wired together. Supports for the joint should be used when the pavement is of such width that the installing bar deflects. On wide streets every joint should be checked as to crown with sighting T's. When necessary to have joint plates in two sections, the contractor should arrange with the manufacturer to have holes drilled in the abutting ends of the plates so that the plates may be securely wired or strapped together. As the joint plates usually do not fit tight to the installing bar, a 1/4-in shim is placed under each end of the installing bar, to insure that the plates are not covered by the concrete.

"**Mixing and Placing Concrete.** The method of MEASURING materials for the concrete, including water, should be one which will insure accurate proportions of each of the ingredients at all times. It is recommended that a sack of Portland cement, containing 94 lb net, be considered as equivalent to 1 cu ft.

"The PROPORTIONS should not exceed 5 parts of fine and coarse aggregate, measured separately, to 1 part of Portland cement, and the fine aggregate should not exceed 40% of the mixture of fine and coarse aggregates.

"AGGREGATES. Bank run material shall not be used. Proportioning based on sieve analysis or by relative density tests is not practical for concrete pavements except

where laboratory direction is available. But where proper facilities are available, the above proportions should be varied as the tests warrant.

"MIXING. The ingredients should be mixed in a batch mixer of approved style, and the size of the batch should not exceed the rated capacity of the mixer. The mixing should be continued for at least 1 minute after all materials are in the mixer and before any of the concrete is discharged. The speed of the mixer should not exceed 16 rev per min; the number of revolutions per batch should not be less than 10; however, the time, and not the number of revolutions, should be the factor for determining proper mixing, in order to distribute the water thru the batch.

"CONSISTENCY. The practice is to mix concrete entirely too wet. The consistency should be such as not to require tamping, but not so wet as to cause the separation of the mortar from the aggregate in handling and placing. The strength and wearing qualities of the concrete are vitally lessened by an excess of water in mixing.

"PLACING. If the subgrade has been disturbed by teaming or from other causes, it should be brought to its former surface, and thoroly saturated with water. The concrete should be deposited rapidly to the required depth and width. The section should be completed to a transverse joint, without the use of intermediate forms or bulkheads, or a transverse joint may be placed at the point of stopping of the work. In case the mixer breaks down the concrete should be mixed by hand to complete the section. Where reinforcement is used it should be embedded in the concrete before the concrete has begun to harden; and the concrete above the reinforcement should be placed within 20 min after the placing of the concrete below. In two-course pavements the top should be placed within 20 min after the placing of the bottom.

"FINISHING. The surface of the concrete should be struck off by means of a template moved with a combined longitudinal and transverse motion. The excess material that accumulates in front of the template should be uniformly distributed over the surface of the pavement except near the transverse joint, when the excess material should be removed. The concrete adjoining the transverse joint shall be dense, and any depressions in the surface shall be filled with concrete of the same composition as the body of the work. After being brought to the established grade with a template, the concrete should be finished to true surface with a wood float, used from a suitable bridge. A metal float, trowel, should not be used. Brooming of the surface is not necessary, and grooves are objectionable even on grades.

"Retempering of mortar or concrete which has partly hardened, that is, mixing with additional materials or water, is strongly condemned and should not be permitted.

"Protection and Curing. Even the best concrete may be seriously damaged by too rapid drying out, early exposure to low temperature, or by being opened to traffic at too early a period. Hot sun and drying winds are most likely to dry out the concrete too rapidly, thus causing shrinkage cracks or causing a surface which will not wear well under traffic. The use of a canvas covering will be found effective in overcoming this condition. Sprinkling should also be employed as soon as the concrete is hard enough to prevent the surface from being pitted. An earth covering or protection by ponding should be employed after the first day. Under most favorable conditions such protection should be given to the pavement for at least 2 weeks. Water should be added during this period to keep the concrete wet. In cool weather it is often advisable to omit the earth covering, thus allowing the concrete to harden more rapidly. Sprinkling should not be omitted during the day in case the surface shows a tendency to dry out. When there is danger of frost, sprinkling should be omitted and a covering of canvas or of straw and canvas used. Placing concrete pavements in temperatures at or near freezing is not advisable; but if in special cases such work is unavoidable, the water and aggregate should be heated and fresh work protected, and precautions taken to protect the concrete from freezing for at least 10 days. Chemicals should not be used to lower the freezing temperature of the mixture. See (23a). Concrete should not be deposited on a frozen subgrade.

"Opening to Traffic. Under most favorable conditions a concrete pavement should not be opened to traffic in less than 2 weeks after the last concrete has been placed, and when conditions permit this interval should be increased to 4 weeks.

"Where the materials most readily available are such as to give good construction in one-course pavement, this Conference recommends that the one-course be used.

"The Integral Curb for concrete street pavements is recommended in preference to straight curb or combined curb and gutter. Such construction eliminates the

longitudinal joint along the curb, and maintains a permanent grade and alignment. Precaution should be taken to insure that the curb is thoroly bonded to the pavement proper. The integral curb can be used on wide as well as on narrow streets.

"**Specifications.** Since no specifications were considered by the Conference, the Standard Specifications for Pavements and Roadways of the Am. Concrete Inst. are recommended."

For a Tabular Comparison of Specifications of Coarse Aggregates, see (59). For additional specifications covering materials for cement-concrete for pavements, see Art. 10.

The Am. Concrete Inst. 1917 Specifications for One-Course Cement-Concrete Pavement for Roads are as follows:

"**Materials.** CEMENT. The cement shall meet the requirements of the Standard Specifications and Tests for Portland Cement, adopted by the Am. Soc. Test. Mat., Sept. 1, 1916, with all subsequent amendments and additions thereto adopted by said Society and by this Institute. See (69c).

"AGGREGATES. Before delivery on the job, the contractor shall submit to the engineer a 50 lb sample of each of the fine and coarse aggregates proposed for use. The samples shall be tested and if found to pass the requirements of the specifications similar material shall be considered as acceptable for the work. Aggregates containing frost or lumps of frozen material shall not be used.

"Fine aggregate shall consist of natural sand or screenings from hard, tough durable crushed rock or gravel, consisting of quartzite grains or other equally hard material, graded from fine to coarse with the coarse particles predominating. Fine aggregate, when dry, shall pass a screen having 4 meshes per lin in; not more than 25% shall pass a sieve having 50 meshes per lin in, and not more than 5% shall pass a sieve having 100 meshes per lin in. Fine aggregate shall not contain vegetable or other deleterious matter, nor more than 3% by weight of clay or loam. Routine field tests shall be made on fine aggregate as delivered. If there is more than 7% of clay or loam by volume in 1 hour's settlement after shaking in an excess of water, the material represented by the sample shall be rejected. Fine aggregate shall be of such quality that mortar composed of 1 part Portland cement, and 3 parts fine aggregate, by weight, when made into briquettes, shall show a tensile strength, at 7 and 28 days, equal to or greater than the strength of briquettes composed of 1 part of the same cement and 3 parts standard Ottawa sand by weight. The percentage of water used in making the briquettes of cement and fine aggregate shall be such as to produce a mortar of the same consistency as that of the Ottawa sand briquettes of standard consistency. In other respects all briquettes shall be made in accordance with the methods outlined in the Standard Specifications and Tests for Portland Cement, adopted by the Am. Soc. Test. Mat., Sept. 1, 1916.

"Coarse aggregate shall consist of clean, hard, tough, durable crushed rock or pebbles graded in size, free from vegetable or other deleterious matter, and shall contain no soft, flat or elongated particles. The size of the coarse aggregate shall be such as to pass a 2-in round opening and shall range from 2 in down, not more than 5% passing a screen having 4 meshes per lin in and no intermediate sizes shall be removed.

"MIXED AGGREGATE. Crusher run stone, bank run gravel or artificially prepared mixtures of fine and coarse aggregate shall not be used.

"WATER shall be clean, free from oil, acid, alkali or vegetable matter.

"All REINFORCEMENT shall be free from excessive rust, scale, paint or coatings of any character which will tend to destroy the bond.

"JOINT FILLER shall consist of prepared strips of fiber matrix and bitumen, or similar material of approved quality, ¼ in in thickness. Where the joints are protected with metal plates the joint filler shall be made to conform to the cross-section of the pavement, and where unprotected joints are used, the width of the joint filler shall be at least ½ in greater than the thickness of the pavement at any point. Prior to submitting bid the contractor shall obtain approval of the engineer for the joint filler which he proposes to use.

"JOINT PROTECTION PLATES. Soft steel plates for the protection of the edges of the concrete at transverse joints shall be not less than 2½ in in depth and not less than ⅛ in nor more than ¼ in average thickness. The plates shall be of such form as to provide for rigid anchorage to the concrete. The type and method of installation of joint protection plates shall be approved by the engineer.

"SHOULDERS. Materials for the construction of shoulders shall be described as desired by the engineer.

"Grading shall include all cuts, fills, ditches, borrow pits, approaches and all earth or rock moving for whatever purpose where such work is an essential part of or necessary to the prosecution of the contract.

"ENGINEER'S STAKES will be set by the engineer for the center line, side slopes, finished grade and other necessary points properly marked for the cut or fill. When the established grade is approached the final grade stakes will be set for which............ days' notice must be given to the engineer.

"FREE HAUL. Excess material shall be disposed of as directed by the engineer, the free haul not to exceed..........feet.

"OVER-HAUL. Materials hauled a greater distance than the free haul from the place of excavation shall be paid for at the rate of.......... cents per cubic yard for each additional..........feet.

"CUTS AND FILLS. In cuts the final grade shall be obtained by rolling with a roller weighing not less than 5 nor more than 10 tons. When a fill of 1 ft or less is required to bring the surface to grade, all vegetable matter shall be removed before making the fill. Embankments shall be formed of earth or other approved materials and shall be constructed in successive layers, the first of which shall extend entirely across from the toe of the slope on one side to the toe of the slope on the other side and successive layers shall extend entirely across embankments from slope to slope. Each layer, which shall not exceed 1 ft in depth, shall be thoroly rolled with a roller weighing not less than 5 nor more than 10 tons. The roller shall pass over the entire area of each layer of the fill at least twice. The sides of the embankment shall be kept lower than the center during all stages of the work and the surface maintained in condition for adequate drainage. The use of muck, quicksand, soft clay or spongy material which will not consolidate under the roller, is prohibited. When the material excavated from the cuts is not sufficient to make the fills shown on the plans, the contractor shall furnish the necessary extra material to bring the fills to the proper width and grade. When the earth work is completed, the cross-section of the road-bed shall conform to the cross-sectional drawings and profile attached hereto.

"All SLOPES must be properly dressed to lines given by the engineer.

"Drainage. The contractor shall construct such drainage ditches as will insure perfect surface and subsurface drainage during construction, and such work shall be completed to the satisfaction of the engineer, prior to the preparation of the road-bed, as herein specified.

"TILE DRAINS shall be placed as shown in the drawings attached hereto. Tile to be laid in a trench at least................ inches wide and..................... feet deep below the established grade of the finished road. Such trench shall be backfilled with crushed stone or pit run gravel, with fine material removed, which, after light tamping, shall be.................... inches in depth.

"OPEN DITCHES must be constructed along the concrete pavement as shown on the attached drawing; the dimensions, side slopes and grade of said ditches being as shown on the cross-section drawings and profile attached hereto. At the time of the acceptance of the road, or when concreting is discontinued for the winter, the ditches must be in perfect condition with clean slopes and bottom, containing no obstructions to the flow of water.

"The Subgrade shall be brought to a firm density by rolling the entire area with a self-propelled roller. All portions of the surface of the subgrade, which are inaccessible to the roller, shall be thoroly tamped with a hand tamp weighing not less than 50 lb, the face of which shall not exceed 100 sq in in area. All soft, spongy or yielding spots and all vegetable or other perishable matter shall be entirely removed and the space refilled with suitable materials. When the concrete pavement is to be constructed over an old road-bed composed of gravel or macadam, the old road-bed shall be entirely loosened and the material spread for the full width of the road-bed and rolled. All interstices shall be filled with fine material and rolled to make a dense, tight surface of the road-bed.

"ACCEPTANCE. No concrete shall be deposited until the subgrade is checked and accepted by the engineer.

"Forms. MATERIALS. Metal or wooden forms shall be free from warp, of sufficient strength to resist springing out of shape, and shall be equal in width to the thickness

of the pavement at the edges. Wooden forms shall be of not less than 2-in stock, and shall be capped with 2-in angle irons.

"SETTING. The forms shall be well staked or otherwise held to the established line and grades, and the upper edges shall conform to the established grade of the road.

"TREATMENT. All mortar and dirt shall be removed from forms before they are used.

"**Pavement Section.** WIDTH, THICKNESS OF CONCRETE AND CROWN. The concrete pavement shall be .... feet wide, ... inches in depth at center, and .... inches in depth at the sides. The finished surface shall conform to the arc of a circle, as shown on the plans attached hereto.

"NOTE: The thickness of the concrete at the edges shall be not less than 6 in. The crown shall be not less than 1/100 nor more than 1/50 of the width.

"**Joints.** WIDTH AND LOCATION. Transverse joints shall be ¼ in in width and shall be placed across the pavement perpendicular to the center line, not more than 36 ft apart. All joints shall extend thru the entire thickness of the pavement and shall be perpendicular to its surface. All catch-basins, manhole tops, poles or other fixed objects which project thru the pavement shall be separated from the concrete by joint filler.

"JOINT FILLER. All joints shall be formed by inserting during construction and leaving in place the required thickness of joint filler which shall extend thru the entire thickness of the pavement.

"PROTECTED JOINTS.* The concrete at all transverse joints shall be protected with joint protection plates which shall be rigidly anchored to the concrete. The upper edges of the plates shall be even with each other and the adjoining surface of the concrete. All steel plates varying more than ¼ in from the finished surface of the concrete, as shown on the plans attached hereto, shall be ground to meet the specified requirements, or slabs in which such plates occur shall be removed and replaced with new material by the contractor at his expense.

"UNPROTECTED JOINTS.* All transverse joints shall extend thru the entire thickness of the pavement and the filler shall project not less than ½ in above the finished surface. Before the road is opened to traffic, joint filler shall be cut off to a height of ¼ in above the surface of the road.

"**Measuring Materials and Mixing Concrete.** MEASURING MATERIALS. The method of measuring the materials for the concrete, including water, shall be one which will insure separate and uniform proportions of each of the materials at all times. A sack of Portland cement, 94 lb net, shall be considered 1 cu ft.

"MIXING. The materials shall be mixed in a batch mixer approved by the engineer, and irrespective of the size of the batch and rate of speed used, mixing shall continue after all materials are in the drum for at least 1 min before any part of the batch is discharged from the drum. The drum shall be completely emptied before receiving material for the succeeding batch. The volume of the mixed material used per batch shall not exceed the manufacturer's rated capacity of the drum in cubic feet of mixed material.

"RETEMPERING. Retempering of mortar or concrete which has partly hardened; that is, remixing with or without additional materials or water, shall not be permitted.

"PROPORTIONS. The concrete shall be mixed in the proportions of 1 sack of Portland cement to not more than 2 cu ft of fine aggregate and not more than 3 cu ft of coarse aggregate, and in no case shall the volume of the fine aggregate be less than one-half the volume of the coarse aggregate. A cubic yard of concrete in place shall contain not less than 1.7 barrels of cement. The engineer shall compare the calculated amount of cement required according to these specifications and plans attached hereto with the amounts actually used in each section of concrete between successive transverse joints, as determined by actual count of the number of sacks of cement used in each section. If the amount of cement used in any three adjacent sections, between transverse joints, is less by more than 2%, or if the amount of cement used in any one section is less by more than 5% of the amount hereinbefore required, the contractor

"*NOTE: When the specification Protected Joints is to be used, Unprotected Joints should be omitted, and vice versa.

shall remove all such sections and replace the same with new materials, according to these specifications, at his expense.

"CONSISTENCY. The materials shall be mixed with sufficient water to produce a concrete which will hold its shape when struck off with a template. The consistency shall not be such as to cause a separation of the mortar from the coarse aggregate in handling.

"Reinforcing. Concrete pavements 20 ft or more in width shall be reinforced. The reinforcement shall have a weight of not less than 28 lb per 100 sq ft. The ratio of effective areas of reinforcing members at right angles to each other may vary from 1:1 to 4:1. The spacing between parallel lines of reinforcing members shall not be more than 8 in. A reduction of 3 lb from the weight specified shall be allowed for those types of reinforcement not requiring extra metal at intersections.

"NOTE: The committee is of the opinion that the weight of reinforcement for streets over 25 ft wide should be greater than 28 lb per 100 sq ft.

"Reinforcing metal shall be placed not less than 2 in from the finished surface of the pavement and otherwise shall be placed as shown on the drawings attached hereto. The reinforcing metal shall extend to within 2 in of all joints, but shall not cross them. Adjacent widths of fabric shall be lapped not less than 4 in when the lap is made perpendicular to the center line of the pavement and not less than 1 ft when the lap is made parallel to the center line of the pavement, and in most cases the use of reinforcement in pavements 16 ft wide is good practice.

"Placing Concrete. Immediately prior to placing the concrete, the subgrade shall be brought to an even surface. The surface of the subgrade shall be thoroly wet but shall show no pools of water when the concrete is placed. After mixing, the concrete shall be deposited rapidly upon the subgrade, to the required depth and for the entire width of the pavement in successive batches and in a continuous operation without the use of intermediate forms or bulkheads between expansion joints. If concrete is placed in two courses, as when reinforcement is used, any dirt, sand or dust which collects on the base course, shall be removed before the top course is placed. The concrete above the reinforcement shall be placed immediately after mixing and in no case shall more than 45 min elapse between the time that the concrete below the reinforcement has been mixed and the concrete above the reinforcement is placed. In case of a breakdown, concrete shall be mixed by hand to complete the section or an intermediate transverse joint placed as hereinbefore specified at the point of stopping work. Any concrete in excess of that needed to complete a section at the stopping of work shall not be used.

"FINISHING. The concrete shall be brought to a proper contour by any means which will insure a compact dense surface. Any holes left by removing any material or device used in constructing joints shall be filled immediately with concrete from the latest batch deposited on the subgrade. Concrete adjoining metal protection plates at transverse joints shall be dense in character and shall be given a smooth finish with a steel trowel for a distance of 6 in on each side of the joints. The concrete adjacent to unprotected joints shall be finished with a wood float, which is divided thru the center and which will permit finishing on both sides of the filler at the same time. Concrete shall be finished in a manner thoroly to compact it and produce a surface free from depressions or inequalities of any kind. The finished surface of the pavement shall not vary more than ¼ in from the specified contour.

"NOTE: It is recommended that the contractor be required at the end of each day's work to stamp in the surface of the concrete, with letters 1½ to 2 in high and ¼ in deep, the date and his name.

"Protection. CURING AND PROTECTION. Except as hereinafter specified, the surface of the pavement shall be sprayed with water as soon as the concrete is sufficiently hardened to prevent pitting, and shall be kept wet until an earth or other approved covering is placed. As soon as it can be done without damaging the concrete, the surface of the pavement shall be covered with not less than 2 in of earth or other material approved by the engineer, which cover shall be kept wet for at least 10 days. When deemed necessary or advisable by the engineer, freshly laid concrete shall be protected by canvas until such covering can be placed. Under the most favor conditions for hardening in hot weather the pavement shall be closed to traffic least 14 days, and in cool weather for an additional time, to be determine engineer. When the average temperature is below 10° C (50° F), sprinklin

ering of the pavement may be omitted at the discretion of the engineer. The contractor shall erect and maintain suitable barriers to protect the concrete from traffic and any part of the pavement damaged from traffic or other causes, occurring prior to its official acceptance, shall be repaired or replaced by the contractor at his expense, in a manner satisfactory to the engineer. Before the pavement is thrown open to traffic the covering shall be removed and disposed of as directed by the engineer.

"COLD WEATHER WORK. Concrete shall not be mixed nor deposited when the temperature is below freezing. If, at any time during the progress of the work, the temperature is, or in the opinion of the engineer will within 24 hr drop to 2° C (35° F), the water and aggregates shall be heated, and precautions taken to protect the work from freezing for at least 10 days. In no case shall concrete be deposited upon a frozen subgrade.

"**Shoulders.** CONSTRUCTION. When shoulders are required, they shall be built upon the properly prepared subgrade, as shown on the profile and cross-sectional drawings attached hereto. The work shall be done to the entire satisfaction of the engineer."

Am. Concrete Inst. 1917 Specifications for One-Course Cement-Concrete Pavement for Streets. Note: All essentials of the specifications for One-Course Cement-Concrete Pavement for Roads applicable to street pavements, except those having the same titles as sections hereafter given, form a part of these specifications.

Materials. JOINT FILLER. Essentially the same as for One-Course Cement-Concrete Pavement for Roads and, in addition, as follows: "The filler for longitudinal joints along the curb, where a separate curb is used, shall, at the discretion of the engineer, consist of the same material as specified for the transverse joints or of bitumen which will not become soft enough to flow in hot weather or brittle in cold weather. The thickness of longitudinal joints filled with bitumen shall be not less than ¼ nor more than ¾ in.

Grading. CUTS AND FILLS. Essentially the same as for One-Course Cement Concrete Pavements for Roads and, in addition, as follows: "All approaches connecting the specified pavement with other streets or alleys intersecting shall also be cut or filled, and secured from settlement, to form a slope of not more than 1 vertical to 10 horizontal, as shown on the profile and plans attached hereto.

"**Drainage.** CATCH-BASINS. All catch-basin and manhole tops and all covers or openings of any kind shall be adjusted to the grade by the contractor at the price shown under this item in his bid.

"**Forms.** SETTING. The forms shall be well staked or otherwise held to the established line and grades. Where the curb is to be constructed integrally with the pavement, the upper edge of the side forms shall conform to the top of the curb.

"**Pavement Section.** WIDTH, THICKNESS OF CONCRETE AND CROWN. The concrete pavement shall be............feet wide from face to face of curb,............inches in depth at the center and..............inches in depth at the sides. The finished surface shall conform to the arc of a circle as shown on the plans attached hereto.

"NOTE: The thickness of the concrete at the sides shall be not less than 6 in and at the center not less than 2 in more than the thickness at the sides. When pavements 20 ft or less in width are to be built on approximately level ground and a flat subgrade is to be used, sufficient fall for drainage at the sides of the pavement along the curb shall be provided by giving the road-bed the same grade as that proposed for the gutter. The crown shall be not less than 1/100 nor more than 1/50 of the width.

Joints. WIDTH AND LOCATION. Same as for One-Course Cement-Concrete Pavement for Roads except as follows: "A longitudinal joint not less than ¼ in wide shall be constructed between the curb and the pavement where a separate curb is used. All joints shall extend thru the entire thickness of the pavement and curb, when integral curb is specified and shall be perpendicular to the surface of the pavement. In pavements with integral curb, the joint shall be continuous in a straight line thru pavement and curb.

"JOINT FILLER. All transverse joints shall be formed by inserting during construction and leaving in place the required thickness of prepared strips of fiber matrix and bitumen or similar material of approved quality which shall extend thru the entire thickness of the pavement and the entire thickness and height of the integral curb when the latter is specified. Longitudinal joints along the curb, where a separate

curb is specified, shall, at the discretion of the engineer, be formed in the same manner as transverse joints or constructed by filling with bitumen as before specified.

"**Integral Curb.** CONSTRUCTION. An integral curb shall be constructed, as shown on the attached drawings, to the established grade and in a continuous line on each side of the street ....feet from and parallel with the center line thereof, except at all intersections of streets, alleys and driveways where it shall be returned to the street line, and at these intersections it shall be rounded to such a radius as the engineer may direct. The concrete for integral curbs shall be of the same materials and proportions as that required for the pavement. After striking off the pavement, the concrete for that portion of the integral curbs above the gutter line shall be immediately deposited. The top and inside surface of integral curbs shall be given a smooth finish and completed with the pavement to the point of stopping each day's work."

"NOTE: Above paragraph to be omitted if separate curb is specified."

Am. Concrete Inst. 1917 Specifications for Two-Course Cement-Concrete Pavement for Streets. Note: All essentials of the specifications for One-Course Cement-Concrete Pavement for Streets, except those having the same titles as sections hereinafter given, form a part of these specifications.

Aggregates. The same as for One-Course Cement-Concrete Pavement for Streets and, in addition, as follows:

"NO. 1 AGGREGATE FOR WEARING COURSE: No. 1 aggregate for the wearing course shall consist of clean, hard, tough, durable crushed rock or pebbles, free from vegetable matter, and shall contain no soft, flat or elongated particles. It shall pass, when dry, a screen having ½-in openings and not more than 10% shall pass a screen having ¼-in openings.

"NO. 2 AGGREGATE FOR WEARING COURSE: No. 2 aggregate for the wearing course shall consist of clean, hard, tough, durable crushed rock or pebbles graded in size, free from vegetable or other deleterious matter, and shall contain no soft, flat or elongated particles. The size of No. 2 coarse aggregate shall be such as to pass a 1-in round opening and shall range from 1-in down, not more than 5% passing a screen having 4-meshes per lin in and no intermediate sizes shall be removed.

Pavement Section. WIDTH, THICKNESS OF CONCRETE AND CROWN. Essentially the same as for One-Course Cement-Concrete Pavement for Streets and, in addition, as follows:

"NOTE: The thickness of the concrete base at the sides shall be not less than 5 in and at the center not less than 2 in more than the thickness at the sides. The thickness of the wearing course shall be not less than 2 in.

"**Measuring Materials and Mixing Concrete.** CONSISTENCY. The materials for the pavement shall be mixed with only sufficient water to produce a concrete which will hold its shape when struck off with a template. The consistency shall not be such as to cause a separation of the mortar from the aggregate in handling.

"CEMENT REQUIRED. A cubic yard of concrete base in place shall contain not less than 1.4 barrels of cement. A cubic yard of No. 1 Mix Wearing Course in place shall contain not less than 2.97 barrels of cement, and a cubic yard of No. 2 Mix Wearing Course in place shall contain not less than 2.1 barrels of cement. The engineer shall compare the calculated amount of cement required according to these specifications and plans attached hereto with the amounts actually used in each section of concrete, including integral curbs when used, between successive transverse joints, as determined by actual count of the number of sacks of cement used in each section. If the amount of cement used in any three adjacent sections, between transverse joints, is less by more than 2%, or if the amount of cement used in any one section is less by more than 5% of the amount hereinbefore required, the contractor shall remove all such sections and replace the same with new materials, according to these specifications, at his expense.

"**Concrete for Base.** PROPORTIONS. The concrete shall be mixed in the proportions of 1 sack of Portland cement to not more than 2½ cu ft of fine aggregate, and not more than 4 cu ft of coarse aggregate, and in no case shall the volume of the fine aggregate be less than one-half the volume of the coarse aggregate.

PLACING CONCRETE. Essentially the same as for One-Course Cement-Concrete Pavement for Streets and, in addition, as follows: "The concrete shall be brought to

an even surface, the thickness of the wearing course below the established grade of the pavement. If dirt, sand or dust collects on the base it shall be removed before the wearing course is applied. The reinforcing metal shall be placed upon and slightly pressed into the concrete base immediately after it is placed.

"Concrete for Wearing Course. PROPORTIONS FOR MIXTURE NO. 1*. The concrete for the wearing course shall be mixed in the manner hereinbefore specified in the proportions of 1 sack of Portland cement to not more than 1 cu ft of fine aggregate, and not more than 1½ cu ft of No. 1. Aggregate for Wearing Course and in no case shall the volume of the fine aggregate be less than one-half the volume of the No. 1 Aggregate for Wearing Course.

"PROPORTIONS FOR MIXTURE NO. 2.* The concrete for the wearing course shall be mixed in the manner hereinbefore specified in the proportions of 1 sack of Portland cement to not more than 1½ cu ft of fine aggregate and not more than 2½ cu ft of No. 2. Aggregate for Wearing Course hereinbefore specified, and in no case shall the volume of the fine aggregate be less than one-half the volume of No. 2 Aggregate for Wearing Course.

"PLACING. The wearing course shall be placed immediately after mixing and in no case shall more than 45 min elapse between the time that the concrete for the base has been mixed and the time the wearing course is placed.

Integral Curb. Essentially the same as for One-Course Cement-Concrete Pavement for Streets and, in addition, as follows: "The concrete for that portion of the integral curbs above the base shall be of the same materials and proportions as that specified for the wearing course."

Am. Concrete Inst. 1917 Specifications for One-Course Cement-Concrete Pavement for Alleys. Note: All essentials of the specifications for One-Course Cement-Concrete Pavement for Streets, except those having the same titles as sections hereinafter given, form a part of these specifications.

"Forms. MATERIALS. Metal or wooden forms shall be free from warp, of sufficient strength to resist springing out of shape, and shall be equal in width to the thickness of the pavement at the edges. Wooden forms shall be of not less than 2-in stock. Where the pavement is laid adjacent to buildings, fences or other structures, the side forms may be omitted at the direction of the engineer, but a joint must be constructed as hereinafter specified, between the pavement and such structure.

"Pavement Section. WIDTH, THICKNESS OF PAVEMENT AND CROSS-SECTION. The width of the pavement shall be................feet inches, and not less than 6 in uniform thickness. In cross-section the finished surface shall have a uniform pitch toward the center line, except that the center 12 in shall be rounded to the arc of a circle which is tangent to the surface of the concrete at points 6 in on each side of the center line, as shown in the plans attached hereto. The dish shall not exceed 1/30 of the width of the pavement."

Am. Soc. Mun. Imp. 1917 Specifications for a One-Course Pavement† are as follows:

"Materials. CEMENT. The cement shall meet the requirements of the Standard Specifications for Portland Cement, adopted by the Am. Soc. Test. Mat., August 16, 1909, with all subsequent amendments and additions thereto adopted by said Society.

"FINE AGGREGATE. Sand. Fine aggregate shall consist of natural sand or screenings from hard, tough, durable crushed rock or gravel, consisting of quartzite grains or other equally hard material graded from fine to coarse, with the coarse particles predominating. Fine aggregate, when dry, shall pass a sieve having 4 meshes per lin in; not more than 25% shall pass a sieve having 50 meshes per lin in, and not more than 5% shall pass a sieve having 100 meshes per lin in. Fine aggregate shall not contain vegetable or other deleterious matter nor more than 3% of clay or loam. Fine aggregate shall be of such quality that mortar composed of 1 part Portland cement and 3 parts of fine aggregate, by weight, when made into briquettes, shall show a tensile

"*NOTE: When Mixture No. 1 is specified, specifications for Mixture No. 2 should be omitted, and vice versa.

"†Specifications regarding both joints and reinforcement are purposely omitted from these specifications, in order that the freest opportunity may be afforded for their addition, in any particular case, according to the opinions of the engineers in charge, dependent upon local conditions.

strength, at 7 and 28 days, at least equal to the strength of briquettes composed of 1 part of the same cement and 3 parts standard Ottawa sand by weight. The percentage of water used in making the briquettes of cement and fine aggregate shall be such as to produce a mortar of the same consistency as that of the Ottawa sand briquettes of standard consistency. In other respects, all tests shall be made in accordance with the prevailing Report of the Committee on Uniform Tests of Cement of the Am. Soc. C. E.

"COARSE AGGREGATE shall consist of clean, tough, crushed rock or pebbles, or slag of approved quality in graded sizes, free from vegetable or other deleterious matter and containing no soft, flat or elongated particles. The sizes of the coarse aggregate shall be such as to pass a 1½-in round opening, and shall range from 1½ in down, not more than 5% passing a ¼-in round opening, and with no intermediate sizes removed.

"**Proportions.** All proportions of cement, fine aggregate and coarse aggregate shall be determined on the basis of volumetric analysis, with a view to obtaining a uniform density for the resulting concrete. Voids in the fine aggregate shall be determined by saturation and not less than 20% more cement shall be employed than the volume of voids thus determined; in no case shall the proportions of cement and fine aggregate be leaner than 1: 2. The voids in the coarse aggregate shall be determined by saturation and not less than 20% more mortar shall be employed than the volume of voids thus determined.

"**Water** shall be clean, free from oil, acid, alkali, vegetable matter and other deleterious substances.

"**Subgrade.** CONSTRUCTION. The bottom of the excavation or the top of the fill when completed shall be known as the subgrade and shall be at all places true to the elevation as shown on the plans attached hereto. The subgrade shall be brought to a firm, unyielding surface by rolling the entire area with a self-propelled roller weighing not less than 5 tons, and all portions of the surface of the subgrade, which are inaccessible to the roller, shall be thoroly tamped with a hand tamp weighing not less than 50 lb, the face of which shall not exceed 100 sq in in area. All soft, spongy, or yielding spots and all vegetable or other perishable matter shall be entirely removed and the space refilled with suitable material. When considered necessary or of assistance in producing a compact, solid surface, the subgrade before being rolled shall be well sprinkled with water. When the concrete pavement is to be constructed over an old pavement composed of gravel or macadam, the latter shall be entirely loosened and the material spread for the full width of the pavement and rolled. All interstices shall be filled with fine material and rolled to make a dense, tight surface.

"ACCEPTANCE. No concrete shall be deposited until the subgrade is checked and accepted by the engineer.

"**Forms.** MATERIALS. Where forms are required, they shall be free from warp, of sufficient strength to resist springing out of shape. Wooden forms shall be of not less than 2-inch stock.

"SETTING. The forms shall be well staked or otherwise held to the established line and grades. Where the curb is to be constructed integrally with the pavement, the upper edge of the side forms shall conform to the top of the curb.

"TREATMENT. All mortar and dirt shall be removed from the forms that have previously been used. Precautions shall be taken to prevent leaks thru side forms that would allow the cement or mortar to be carried out of the coarser aggregate along the edges of the roadway.

"**Measuring Materials and Mixing Concrete.** MEASURING MATERIALS. The method of measuring the materials for the concrete, including water, shall be one which will insure separate and uniform proportions of each of the materials at all times. A bag of Portland cement, 94 lb net, shall be considered 1 cu ft.

"MIXING. The materials shall be mixed in a batch mixer of approved type and mixing shall continue after all materials are in the drum for at least 1 min at a minimum speed of 12 rev per min. The drum shall be completely emptied before receiving materials for successive batches.

"RETEMPERING of mortar or concrete which has partially hardened, that is, remixing with or without additional materials or water, shall not be permitted.

"**Placing Concrete.** Immediately prior to placing the concrete, the subgrade shall be brought to an even surface. The surface of the subgrade shall be thoroly wetted. After mixing, the concrete shall be deposited rapidly upon the subgrade to the required depth and for the entire width of the pavement in successive batches and in a

continuous operation without the use of intermediate forms or bulkheads between expansion joints. In case of a breakdown, concrete shall be mixed by hand to complete the section or an intermediate transverse joint placed at the point of stopping work. Any concrete in excess of that needed to complete a section at the stopping of work shall not be used in the work.

"FINISHING. The surface of the concrete shall be struck off for the entire width of the pavement and from back to back of integral curbs when used, by means of a template or strike-board. Any holes left by removing any material or device used in constructing the joint shall be immediately filled with mortar composed of 1 part cement and 2 parts of fine aggregate. Concrete adjoining metal protection plates of transverse joints shall be dense in character and shall be given a smooth finish with a steel trowel for a distance of 6 in on each side of the joints. After being brought to the established grade with the template or strike-board, the concrete shall be finished from a suitable bridge, no part of which shall come in contact with the concrete. If approved by the engineer, the contractor may use a mechanical striking and finishing machine. The concrete shall be finished with a wood float in a manner to thoroly compact it and produce a surface free from depressions or inequalities of any kind. The finished surface of the pavement shall not vary more than ¼ in from the true shape.

"Protection. Excepting as hereinafter specified, the surface of the pavement shall be sprayed with water as soon as the concrete is sufficiently hardened to prevent pitting, and shall be kept wet until an earth or other approved covering is placed. As soon as it can be done without damaging the concrete, the surface of the pavement shall be covered with not less than 2 in of earth or other material approved by the engineer, which cover shall be kept wet for at least 10 days. When deemed necessary or advisable by the engineer, freshly laid concrete shall be protected by the canvas until such covering can be placed. Under the most favorable conditions for hardening in hot weather, the pavement shall be closed to traffic for at least 14 days and in cool weather for an additional time, to be determined by the engineer. At the season of the year when the average temperature is below 10° C (50° F), sprinkling and covering of the pavement may be omitted at the direction of the engineer. The contractor shall erect and maintain suitable barriers to protect the concrete from traffic and any part of the pavement damaged from traffic or other causes, occurring prior to its official acceptance, shall be required or replaced by the contractor at his expense, in a manner satisfactory to the engineer. Before the pavement is thrown open to traffic the covering shall be removed and disposed of as directed by the engineer.

"TEMPERATURE BELOW 2° C (35° F). Concrete shall not be mixed or deposited when the temperature is below freezing. If at any time during the progress of the work the temperature is, or in the the opinion of the engineer will, within 24 hr drop to 2° C (35° F), the water and aggregates shall be heated, and precautions taken to protect the work from freezing for at least 10 days. In no case shall concrete be deposited upon a frozen subgrade."

Am. Soc. Mun. Imp. 1917 Specifications for Two-Course Cement-Concrete Pavement. Note: All essentials of the specifications for One-Course Cement-Concrete Pavement, except those having the same titles as sections hereinafter given, form a part of these specifications.

"Materials. No. 1 Coarse Aggregate for the Wearing Course shall consist of that portion of the coarse aggregate, which, when dry, will pass a ½-in round opening and contain not more than 10% of the fine material which will pass a ¼-in round opening.

"No. 2 Coarse Aggregate for the Wearing Course shall consist of that portion of the coarse aggregate, which will pass a 1-in round opening, ranging in size from 1 in down and containing not more than 5% of fine material that will pass a ¼-in round opening, and with no intermediate sizes removed.

"Proportions. All proportions of cement, fine aggregate and coarse aggregate shall be determined on the basis of volumetric analysis with a view to obtaining a uniform density for the resulting concrete.

"BASE. The voids in the fine aggregate shall be determined by saturation and not less than 10% more cement shall be employed than the volume of voids thus determined; in no case shall the proportions of the cement and fine aggregate be leaner than 1:1½. The voids in the coarse aggregate shall be determined by saturation and not less than 20% more mortar shall be employed than the volume of voids thus determined.

"WEARING SURFACE. The coarse aggregate in the wearing surface shall be No. 1 or No. 2 as specified above. The voids in the fine aggregate shall be determined by saturation and not less than 20% more cement shall be employed than the volume of voids thus determined; in no case shall the proportion of cement to fine aggregate be leaner than 1:2. The voids in the coarse aggregate shall be determined by saturation and not less than 20% more mortar shall be employed than the volume of voids thus determined.

Placing Concrete for Base. Essentially the same as the section on Placing Concrete in specifications for One-Course Cement-Concrete Pavement and, in addition, as follows: "The concrete shall be brought to an even surface, the thickness of the wearing course, below the established grade of the pavement. Workmen shall not be allowed to walk on the freshly laid concrete, and if sand or dust collects on the base, it shall be removed before the wearing course is applied. The reinforcing metal shall be placed upon and slightly pressed into the concrete base immediately after it is placed.

"**Concrete for the Wearing Course.** MIXTURE NO. 1. The concrete for the wearing course shall be mixed in the manner and of the proportions hereinbefore described, using for the coarse aggregate No. 1 aggregate for the wearing course hereinbefore specified.

"MIXTURE NO. 2. The concrete for the wearing course shall be mixed in the manner and of the proportions hereinbefore described, using for the coarse aggregate No. 2 aggregate for the wearing course, herein specified.

"PLACING. The wearing course shall be placed immediately after mixing, and in no case shall more than 45 min elapse between the time that the concrete for the base has been mixed and the time the wearing course is placed."

16. Construction Cost Data

First Cost depends so much on local conditions that a bald statement in figures is apt to be entirely misleading unless the conditions are well understood or a further statement of them is comprehensively made. The cost of a concrete foundation, even of a thickness as low as 4 in is scarcely ever less than 50 cents per sq yd, and the cost of a concrete roadway could therefore not be less than this figure. On the other hand, a concrete roadway might cost, under unfavorable but possible conditions, as high as $2 per sq yd.

The Report of Com. XII, 1914 Nat. Conf. Concrete Road Building included the following: See also (50m).

"Altho numerous inquiries were sent out by your Committee for information, there has not been received as yet any large amount of cost data except from the Mich. State Dept., Wayne County, and the Ill. Highway Dept. The Committee has therefore confined itself to averaging the cost of work reported in the different States, confining the comparison to the one-course construction. These data are presented herewith in Table V.

"There are also presented four diagrams: (1) showing the distribution of cost data on concrete roads built 1909-1912, as reported by the State Highway Dept. of Mich.; (2) is a similar diagram compiled from cost data reported on the concrete road work done in Wayne County, Mich., in 1912 and 1913; (3) is a similar diagram for the work done in 1912-1913 by the Ill. Highway Comm.; (4) is the average of all the data from which the first three diagrams were made, taking due account of the relative amount of work done in each instance." The information in the diagrams referred to in the Committee's report is given in tabular form below:

Table V.—Average Cost of One-Course Concrete Pavement

State	Cost per Sq Yd
Arizona	$1.20
Arkansas	0.90
California	1.17
Colorado	1.25
Connecticut	1.32
Delaware	1.61
Idaho	1.09
Illinois	1.01
Indiana	1.23
Iowa	1.11
Kansas	1.08
Maine	1.48
Maryland	1.21
Massachusetts	1.29
Michigan	1.27
Minnesota	1.05
Missouri	1.17
Montana	1.83
Nebraska	1.40
New Jersey	1.12
North Dakota	1.26
Ohio	1.22
Oklahoma	1.05
Oregon	1.39
Pennsylvania	1.16
Tennessee	1.20
Washington	1.31
West Virginia	1.32
Wisconsin	1.06
Average Total	$1.24
Weighted Total Average	$1.19

Table VI.—Showing Division of Total Costs per Square Yard of One-Course Cement-Concrete Roadways

Item	A Average of 7 Pavements in Michigan, Built 1909–12 from Report by Rogers		B Average of 8 Sections Wayne Co., Michigan, Built 1912–13		C Construction by Illinois Highway Commission 1912–13		Weighted Mean of Columns A, B and C	
Labor								
Mixing and placing...					11.6%			
Unloading and hauling					13.1			
Shaping and trimming					6.8			
Superintendence and miscellaneous......					7.0			
Total.............		43.0%		46.0%		38.5%		44.3%
Materials.............								
Aggregate...........	29.0%		27.0%		25.2%		27.7%	
Cement.............	22.7		19.9		31.7		21.6	
Expansion joints.....	....		....		2.3		6.4	
Miscel. Supplies......	5.3		7.1		2.3			
Total...........		57.0%		54.0%		61.5%		55.7%
Grand total.......		100.0%		100.0%		100.0%		100.0%

It should be noted that in the cost figures given no statement is made as to just what the figures include, that is, whether costs per square yard cover simply the furnishing, mixing and placing of the concrete itself, or whether they also cover the incidental work of preparing the subgrade, finally trimming up the shoulders, the overhead charges, etc. Further in applying to estimates the information given by the percentage table, it should be remembered that these percentages have been obtained from figures of cost not varying widely from an average figure and that the division into percentages of total cost might be materially altered where it could reasonably be expected that the total figure would for any reason vary greatly from the average on which those given are based. Further information as to costs reported may be had by reference to (17), (22), (26a), (28a), (32), (38) and (52a). For a discussion of the problems of estimating costs, see (50t).

Cost Analysis of Two-Course Pavement (22). "The following detailed cost analysis is for a 1:1½:3 concrete slab 6 in thick with a No. 29 American wire reinforcement placed 2 in from the top of the pavement. Transverse expansion joints were located at 33-ft intervals, and a longitudinal joint was placed along the middle of the 48-ft street between the 8-ft parkings. A ⅜-in felt strip was placed between the plates and in the joints without plates along the gutters. Weather conditions were, on the whole, favorable. The average rate of progress maintained while working was 720 sq yd per day of 8 hr. Including delays by rain and repairs, the average rate for the entire period was only 500 sq yd per day. Deposition of 864 sq yd was the largest day's work. Labor for mixing and placing concrete cost per sq yd = 79.75 ÷ 720 = $0.111. Plowing with steam roller in well compacted road cost 1 cent per sq yd for each time over. Two or three times over was the rule. Rough grading cost 18 cents per sq yd, exclusive of plowing. Fine grading cost 3 cents per sq yd. Rolling with 10-ton roller cost 0.3 cent per sq yd.

Table VII.—Cost Analysis 6-in Pavement per Square Yard

Materials		
Cement, 0.32 bbl at $1.20, f. o. b. cars........................	$0.384	
Sand, 0.080 cu yd at $1.10, delivered........................	0.088	
Stone, 0.14 cu yd at $1.21, f. o. b. cars........................	0.169	
Wire reinforcement at $0.76 per 100 sq ft........................	0.070	
Joint material at $0.15 per lin ft........................	0.050	
Total materials........................		$0.761

Labor

Grading, 12 in of excavation on average	$0.250	
Unloading and hauling materials 0.5 miles:		
Cement	0.032	
Stone	0.039	
Wire	0.005	
Joints	0.003	
Mixing and placing concrete	0.111	
Spreading and removing earth covering, 2 in thick	0.008	
Sprinkling, for 10 days	0.005	
Total labor		0.453

Plant and Supplies

Mixer rental at $10 per day	$0.020	
Fuel, oil and repairs	0.010	
Canvas, boots and other supplies and tools	0.020	
Total, plant and supplies		0.050
Overhead		0.050
Total cost per square yard		$1.314

Detailed Labor Cost Mixing and Placing Concrete

16 men shoveling and wheeling at 25 cents per hr	$32.00
2 men handling cement at 25 cents per hr	4.00
2 men handling wire and joints at 25 cents per hr	4.00
4 men handling strike-board at 25 cents per hr	8.00
5 men shoveling concrete around chute at 25 cents per hr	10.00
1 foreman at 50 cents per hr	4.00
Engineer and fireman on mixer, per hr	6.00
2 finishers at 50 cents per hr	8.00
Superintendent and timekeeper, ½ time	3.75
Total	$79.75"

Table VIII.—Character and Cost of Cement-Concrete Pavements Laid in 1915 in Several Cities

From *Engineering and Contracting*, April 5, 1916

City	Sq Yd	Type	Total Thickness in In	Price Per Sq Yd Including Grading	Guarantee in Years	Bottom Course or One-Course: Thickness in In	Bottom Course or One-Course: Proportions

17. Special Types of Cement-Concrete Pavements

Grouted Cement-Concrete Pavements. Grouting the aggregate in place is one of the two general methods of construction which may be said to be in use. This method consists of placing the broken stone, gravel or other coarse aggregate on the prepared subgrade, to its necessary total thickness, and then filling the voids of this material with a mixture of sand, Portland cement and water, called grout. The concrete built in this way is thus built in one course, tho the aggregate may be spread and compacted in two layers, and rolling either before or during the grouting, or both, accompanies the process.

THE HASSAM PAVEMENT is a widely known example of this form of construction. Under the Hassam process, the subgrade is prepared as for macadam, the aggregate spread and rolled as in the case of macadam, and then instead of filling the voids in the aggregate with screenings or fine material by the aid of watering and rolling, the rolled aggregate is grouted with the thin mortar referred to, a light rolling accompanying the grouting. The advantages for this type of pavement are claimed to include the following:

1. A greater degree of compaction of the coarse aggregate and a considerable amount of additional strength in the completed pavement resulting from the mechanical or physical interlocking, brought about by the rolling, of the particles of the aggregate.

2. Greater uniformity in the surface presented to wear resulting from the more even arrangement of approximately the same sised pieces of aggregate in the wearing surface, and the avoidance of pockets greatly different in size of particles in the wearing surface of the aggregate. This is especially apparent where harrowing precedes the rolling and after the latter is completed and broken pieces are removed and replaced.

3. The distribution under the roller of the pieces of the aggregate in the wearing surface so as to present, as in macadam, a flat side against the wear rather than an edge or angle.

4. An advantage in the pavement, so built of a greater resistance to cross-breaking strains and consequently a greater supporting or distributing power over the foundation under excessively heavy loads.

5. A greater resistance to the forces producing expansion and contraction in the pavement thru the greater density and strength created in the pavement by this process, and consequently a less apparent effect of these forces.

6. An absence of the separation so often manifested in two-course pavements and exemplified by the riding of the upper course of one section over the surface of an adjacent section at an expansion joint.

There seems to be good ground for most, if not all, of the claims above enumerated, and the use of the Hassam pavement seems to be growing, in spite of the fact that a royalty of approximately 10 cents per sq yd is charged by the patentees for the use of their patent rights. Frequently this excess of first cost is offset by calling for a Hassam pavement of somewhat less thickness than would be specified for an ordinary concrete pavement, mixed and then deposited in place, under the probably correct assumption that a Hassam pavement 5 in in thickness, is of equal strength in strain supporting or distributing power to a 6-in pavement of ordinary mixed-concrete. The objections or difficulties with a grouted aggregate pavement are those incidental to all grouting work and include those of excess of water, segregation of mixed grout, and in getting the latter properly into its place in the mass.

The Specifications for the Hassam Pavement, as recommended by the Board of Consulting Engineers to the N. Y. Highway Comm. in 1913, are as follows:

"Hassam compressed concrete pavement shall consist of a layer of No. 4 stone, stone passing screens having openings between 2¼ and 3½ in in diameter, spread evenly to the required depth to conform to the established lines, grades and cross-sections, after rolling. This stone shall be thoroly compacted with a 10-ton roller until the voids are reduced to a minimum. The voids shall be filled with a 1:1 grout. The rolling shall be continued during the process of grouting. The grout shall be mixed in a Hassam grout mixer. A thin layer of dustless No. 1 broken stone or fine aggregate shall be spread over the entire surface and rolled until the grout flushes to the surface. Approved expansion joints shall be provided where required."

Criticism of the Above would seem to be fairly made by saying that they are too brief and not sufficiently comprehensive as to many important details. For instance, after the stone are spread, if they are thoroly harrowed before rolling, the uniformity in character of the surface will be much improved and consequently the uniformity of grouting. Then after rolling, if any pockets of broken pieces can be found, removed and replaced with fresh stone similar to those adjacent, the improvement in the results will be worth the effort. See also Art. 12, ROLLING.

Cement-Concrete Cubes. In 1909, J. Y. McClintock, County Engineer of Monroe County, New York, laid some experimental pavements in the effort to reduce the cost of suitable roadways in localities where broken stone and satisfactory gravel for macadam were expensive. A section of the experimental road crust was composed of concrete cubes made from the local gravel, which is reported as soft and not first-class concrete material. The cubes were laid by hand on an old macadam roadway with a cushion coat of fine gravel or sand. They were then rolled and the joints filled with a sandy loam. The traffic on the road is reported as heavy, mixed traffic. In the fall of the year, a great many agricultural engines with sharp lugs passed over the road. The cube surface is reported as wearing down rapidly, after giving a satisfactory surface with good footing in both wet and dry weather for 2 years, at the end of which time it disintegrated in large areas. The following conclusions have been drawn from this experiment.

The small cube form of pavement is flexible under frost action, and is therefore a suitable type over a macadam foundation in northern climates. The edge of the cube pavement can be successfully held with a macadam shoulder, making a gradual transition from the roadway surface to the earthy material and preventing the formation of ruts along the edge of the pavement. The local gravel concrete cubes will not support heavy traffic directly on their surface. In 1911, McClintock again experimented with concrete cubes made from a fair quality of gravel obtained from a pit adjacent to the road. The foundation course was 8 in of local gravel. The traffic over this section is reported as not large in volume but of heavy units, 6-ton trucks using it regularly. The surface of the cube pavements when completed was treated with bituminous materials. At the end of 1913, the road surface was reported in good condition, except a few incipient ruts in places assigned to the probable failure of the foundation under the truck traffic, and it is stated that "the experience with this road indicates, that where the local road material is limited to a good gravel, and where it is considered good policy to spend the road funds locally, or where the cubes are cheaper than imported stone macadam, the concrete cubes protected with a bituminous carpet make a satisfactory surface under a light volume of traffic." It is further stated that "concrete cubes at the present cost" can compete economically in only a few cases with macadam.

Oil-Cement-Concrete Pavements. With an idea of bringing about a reduction in the dustiness from concrete pavements and also to increase the imperviousness of the concrete, and hence to reduce the expansion or contraction movements in the mass, the addition of oil to the concrete mixture has been proposed and to some extent advocated. Experiments, however, have seemed to prove that a weakening in the strength of the con-

crete takes place from the addition of the oil, especially in the earlier part of its life, and that this weakness is appreciable in concrete used for pavements without a protecting carpet. The experiments with oil concrete cubes have particularly emphasized this conclusion. It is agreed that a reduction of the dustiness is secured by the use of the oil, but it may also be secured by the use of the oil over the surface of the pavement instead of in the mixture, and with less deleterious effects to the strength of the concrete. Any additional imperviousness of the concrete by the admixture of the oil is disputed by various experimenters. Many claim that the movements of the mass under expansion and contraction are reduced, but this is not at present substantiated.

Blome Granitoid Pavement. This pavement is essentially a two-course cement-concrete pavement, of which the surface course is made and placed as follows (25):

"After the concrete base has been placed, and before it has begun to set, there shall be immediately deposited thereon the granitoid blocking, which shall be 1¾ in thick. It will contain 1 part of Portland cement and 1½ parts of clean, crushed, monument granite or trap rock. This granite shall be screened, with all dust removed therefrom, utilizing the following composition of this material: 50% of the granite to be of what is known as ¼-in size, 30% of the ⅛-in size and 20% of the 1/16-in size. This proportion of sizes is essential, and must be kept absolutely accurate, as in this lies one of the essential requirements to produce proper results. This material is to be mixed with the cement thoroly, and after being wetted to a proper consistency and deposited on the concrete, shall be worked into brick shapes of approximately 4½ by 9 in, with rectangular surface similar to paving blocks. This will be done by special methods, and utilizing grooving apparatus as employed under the Blome Co.'s patents."

The Vibrolithic Pavement is an attempt to get a desirable increase in the density of ordinary mixed concrete. The following extracts from a description of the so-called Vibrolithic process will explain the idea:

"On a properly prepared subgrade there is placed 6 in of concrete. This concrete is so proportioned, cement to aggregate, as to give the maximum strength. Portland cement has a high coefficient of contraction, a factor to be avoided in concrete work. To add more cement to a good and sufficient mix is to add to the possibility of cracking. Enough cement must be used to secure the bond, but an excess will not answer the questions involved, nor will it increase the abrasive value of the surface. A concrete slab properly proportioned, mixed, watered and placed, will, by necessity, have more or less of its surface composed of unequal amounts of mortar or of stone. Certain small areas will be composed entirely of mortar, others of more stone. The wearing quality of the stone will vary from that of the mortar, thus producing an irregular wearing surface. To overcome this inherent defect in ordinary concrete, Vibrolithic specifications provide the following solution:

"Immediately upon placing, raking and smoothing to a true grade, there is spread upon the surface of the concrete, a coating of trap rock, sufficient to completely load the top inch or two of the mass. Narrow, flexible platforms are placed upon the stone and a vibrator is rolled over the platforms, until their bottom edges are brought to a true grade, and the surfacing stones perfectly imbedded in the slab. In this way the vibrator performs a double function, that of imbedding the stone, while densifying the mass.

"Vibrations are the most effective agents in compacting masses made up of members of angular form; for example, a barrel of tacks can not be compressed into a smaller volume, but a great reduction can be brought about by shaking, trembling, or vibrating the barrel. The same action will occur if the barrel contains an angular aggregate such as is used in concrete formations. This density is the most important requirement in placing concrete; first, to obtain a positive bearing of solid upon solid, and second, to assist chemical action and efficiency by getting the particles to be bound so closely related that crystal and colloidal bonds may be effective. It will be understood that the ties that bind, in concrete, are too small to be seen by the naked eye, hence the importance and value of density."

18. Bituminous Carpets

Various kinds of carpets may be applied to concrete as well as to other pavements, and varying thicknesses may be employed to meet any peculiar conditions. Bearing in mind that a carpet is a layer of appreciable thickness, the only reference that may be needed to the thin applications which are in the nature of varnishes, and similar in their action and effect to the use of varnishes on wooden floors for instance, is the caution to secure in using them such materials and methods of application as will result in a good union between the thin application of varnish and the concrete to which it is applied, and such quality of material as will give the most lasting results. Too thick an application of this character should not be attempted because of the shorter life to the coating thus usually secured. The cohesive qualities of such a varnished coat are usually much greater than its adhesion to the concrete, and consequently if a thick coat is attempted, its separation from the concrete is almost inevitable and it peels off under traffic, or shoves into irregular waves which become more and more apparent and objectionable as traffic continues on the road.

The Desirable Characteristics of This Carpet, both as to composition and thickness, depend largely on local conditions, but certain general principles may be laid down. In the first place, the bituminous material must have sufficient adhesive qualities and its application must be so made as to secure such an adhesion of the carpet to the concrete as will enable the carpet to perform its duties to the best of its ability. Sticky bituminous material is a prime necessity for a successful carpet and equally necessary, in order that the adhesive qualities of the bituminous material may be made the most of, is a clean surface of the concrete before applying the bituminous material. By clean surface of the concrete is meant not only freedom from dirt but also freedom from fine impalpable material usually accompanying concrete surfaces and produced by the disintegration under natural or other forces of the components of the concrete. Further it is most desirable that, so far as possible, the aggregate of the concrete be exposed to contact with the bituminous material in order that the bond between the two may be of the highest. The bond between the bituminous material and the cement mortar in the concrete is far less strong usually than the bond securable between the bituminous material and the coarser aggregate of the concrete.

Secondly, a desirable bituminous material should have the greatest possible permanence in its good qualities, that is, it should not be so susceptible to atmospheric and traffic conditions that it will under them quickly loose its adhesion or cohesion or elasticity.

Thirdly, the bituminous material must not be unduly susceptible to changes in temperature so that it will become soft and inclined to shift about in warm weather, nor become brittle and inclined to be objectionably friable in cold weather. The mineral material used in forming the carpet should be of the toughest quality possible so that it will withstand to the utmost the shocks and wear of traffic. The size of the particles desirable in any case will be influenced by the thickness of the carpet to be laid. Under ordinary conditions, it has been proved desirable to have the mineral particles uniformly as large as practicable for the required thickness, and as free as possible from finer material, the fine material necessary for the best formation of the carpet being readily secured from the disintegration of the coarse material in service. The best carpets seem to be made, other things

being equal, by the use of extremely clean and hard gravel of the proper size for the thickness of the carpet desired. Clean chips crushed from good trap rock frequently do nearly as well as the gravel, and fine sand makes the least desirable carpet. In fact a carpet of fine sand, in order to give even moderate satisfaction, must be of the thinnest possible construction and approach more nearly a varnish coat, or such a coat of paint sanded as is sometimes used to protect wood work.

Thickness of Carpets. Ordinarily, the carpets vary from about 1/8 to perhaps 1/2 in in thickness. Instances have been known where they have even reached 1 in in thickness, while the sheet-asphalt layers have sometimes been laid as thin as 1 1/2 in in thickness directly on the concrete base. These latter have shown a weakness to support more than a moderate amount of traffic. The consensus of opinion seems to be, that this weakness was due to the fact that the layer of sheet-asphalt mixture was attempted to be connected with the concrete foundation by a paint coat rather than thru the medium of the usual binder course. Again, the attempts to build *in situ* the carpet of a greater thickness than 1/2 in have almost always resulted unsatisfactorily, and the few instances of the 1 in carpets above referred to, which were mixed and placed almost identically in the same way as the sheet-asphalt pavements without the binder course, have not shown themselves able to stand satisfactorily more than a moderate amount of traffic. The conclusion therefore is that bituminous carpets are limited in their ability to give satisfactory service under traffic. Another conclusion generally reached is that attempts to build them *in situ* will be unsuccessful if they are not made less than 1/2 in in thickness, and that for carpets of greater thickness than this, especial care must be taken to provide the densest possible mixture for the carpet with the greatest practicable size to the largest particles in it, and at the same time the greatest possible adhesion or connection with its base either thru an efficient paint coat or thru such a means as the binder course usually provided in sheet-asphalt pavements.

The Destruction of the Adhesion of a Carpet to its base may come about in one or more of several ways. The bituminous material may be so changed under service as to lose adhesion and then the shifting tendencies of the traffic break the bond between the carpet and the base. The carpet may be so proportioned, as to lack stability and be susceptible to the shifting tendencies of the traffic. Its movement is then, under the traffic, merely a question of time. In all carpet foundations made of soft stone and particularly perhaps of concrete where the mortar forms a most friable material, the destruction of the bituminous carpet by scaling off in spots or shifting into waves, is most noticeable, and on such foundations, especially the concrete, especial care must be taken to provide such thickness and quality of the carpet as will protect to the utmost the concrete underneath from its natural tendency to become disintegrated under the shocks of traffic. These shocks produce a disintegration of the surface of the concrete beneath the carpet, and on which surface the stability of the carpet must depend by its adhesion to that surface. If this surface becomes disintegrated, the adhesion of the carpet to the mass of concrete is destroyed. This disintegration of the concrete underneath bituminous carpets is especially noticeable under hard tired and animal-drawn vehicles, particularly where the carpet itself lacks the thickness of body necessary for the absorption of the shocks coming on its surface to prevent the disintegration of the concrete surface beneath. Therefore, on concrete roads, it is desirable to provide the highest

quality of carpet securable in order that the disintegration of the concrete surface beneath may be prevented to the utmost. Another argument is now evident for the securing in the concrete itself the greatest possible area of the coarse aggregate in the surface with a minimum of the more friable material.

The Report of Com. VIII, 1914 Nat. Conf. Concrete Road Building (50i) included the following conclusions:

"Fundamentally, it would appear, that the surfacing of a concrete road implies a lack of confidence in the ability of concrete to withstand traffic. Many hold that the concrete of itself should bear the brunt and that the use of a protective medium is a confession that concrete has failed to justify the hopes held out for it. On the other hand are those who contend that a concrete pavement, no matter how well laid, will sooner or later crack and pit in spots, and, since these cracks and pits will be patched with bituminous material, it is wise to prevent this entirely by laying a carpet on the concrete surface. As to the materials and methods suitable for coverings there are equally wide differences of opinion. This is undoubtedly due to lack of sufficient experience. On one point, however, there is a well defined opinion that tar is more suitable for carpet coats than asphalt. On the other hand, there is some testimony that asphalt has given good results.

"It would appear, therefore, that investigations of bituminous surfaces for concrete roads should be divided into two parts:

1. Should concrete roads themselves bear the brunt of the traffic, or should some bituminous material be interposed to take the wear?

2. What has experience shown with reference to different materials and methods of application?

"In conclusion, one point can be safely emphasized. It admits of no discussion. The concrete pavement itself, even if it is to be covered by a bituminous coat, should be laid with as much care as if it were not to be protected. This applies to the preparation of the subgrade, and the proportioning, mixing, laying and curing of concrete."

Los Angeles, Cal. Practice (27b). "The concrete base for this road will be 24 ft in width and 8 in thick. It will be made of 1 : 2 : 4 concrete. This base will rest on a cushion of decomposed granite 5 in thick and 40 ft in width. Shoulders 8 ft wide will be built of decomposed granite on each side of the concrete base. The standard section for most of the Los Angeles County highways is a concrete base 20 ft in width and 5 in in thickness, with 5-ft shoulders. Transverse expansion joints across the full width of the concrete will be placed at 25-ft intervals.

"On the concrete is to be a bituminous carpet of a character common in California roadwork. The specification for the surfacing is worded as follows: After the concrete pavement has been constructed, all dust, mud, earth or foreign material of any kind which may have accumulated upon it shall be removed and the surface flushed with water. When it has become sufficiently hard and dry and in the opinion of the Road Commissioner is ready to receive it, asphaltic oil shall be applied in one application of approximately ½ gal to the sq yd. Directly after the oil has been applied stone screenings or sand shall be uniformly spread upon it in sufficient quantity to combine with the oil without leaving any excess screenings or sand on the finished road surface. The stone screenings or sand are to be spread in a direction parallel with the road and never crosswise. If necessary, from time to time, additional screenings or sand shall be spread, as the Road Commissioner may direct, to cover any oil which may come to the surface, until the final completion and acceptance of the work.

"It is estimated that this road will cost approximately $26 000 per mile. The County of Los Angeles is furnishing all material used in its construction."

MAINTENANCE

19. Methods of Maintenance

Considerable difficulty exists in making repairs to concrete in any form, the main difficulty being to secure a proper union between the new and the old concrete. A depression in a concrete pavement can only be repaired satisfactorily by cutting away sufficient old concrete in the depres-

sion so as to give an area of proper thickness with vertical edges, it being impossible to place new concrete on old with feathered edges, and to have these thin edges unite properly with the old concrete. When the area is cut out with vertical edges, it is impossible to prevent the formation of a perceptible joint in the circumference of the patch and all such joints in the rigid concrete are foci of weakness. The most successful repairs to a cement-concrete pavement are probably made by cutting out the area to be repaired and then filling the hole with bituminous concrete. In an uncarpeted concrete road, this produces unsightly spots and must be regarded as the beginning at least of finally carpeting or otherwise covering the whole of the concrete pavement and thus changing it really from a pavement to a foundation. The importance of these facts makes it wise to regard them carefully before going to much extra expense in construction for a particularly rich mixture for the concrete. In other words, if it is to be expected that, within a few years, the concrete pavement proposed to be laid is to be covered with a carpet of some kind, it will even be better to so draw the specifications for the concrete as to provide for the cheaper form of concrete foundation, and perhaps to allow it temporarily to be used as a roadway pavement, finally surfacing it as conditions make desirable, rather than to provide a much more expensive form of concrete pavement which will permit a longer life perhaps to the concrete, but which will inevitably and eventually require its relegation to the position of a foundation, where a much cheaper form of construction would be equally satisfactory.

The Joints of a Concrete Pavement generally begin to show the wear first and this is particularly true with those joints that accidentally occur in the form of cracks. The wear of the provided joints is intended to be guarded against by special forms of plates, but the marked difference between the wearing qualities of these plates under traffic and of the concrete adjacent to them seems to simply transfer the wear from the joint itself to the area just back of the plates. Where the provided joints are not protected by plates, and in the case of accidental joints or cracks, the edges of the joints or cracks quite quickly chip off and wear away, especially where there is much animal-drawn and hard tired traffic. The usual repair of such joints consists of cleaning them out as well as possible and filling them with bituminous cement.

The Edges of Concrete Pavements, especially where the roadway has been made too narrow to prevent many of the vehicles from turning off the roadway on to the shoulders, are particularly susceptible to disintegration under traffic. If the shoulder material is quite soft, a vehicle may run along for some distance, grinding on the edge of the concrete and wearing it severely before finally climbing back from the rut in the shoulder on to the concrete surface. Not only is the edge of the concrete pavement damaged in such cases, but the rut just outside of the concrete forms a collecting place for water which may accumulate there sufficiently to injure the foundation of the roadway and result in upheavals or cracks in the concrete slab. On all such roads, it is particularly desirable to construct and maintain the shoulders in such a manner as to prevent, as far as possible, the occurrence of the above described defects. For a discussion of maintenance of shoulders, see Art. 4.

Resurfacing an Old Cement-Concrete Road With New Concrete (66). "Grand River Road, Wayne County, Mich., was selected for this experiment as it would receive the severest kind of test, on account of the heavy mixed traffic which uses this high-

way and because the section selected was rough and uneven. This section of road was built in 1910, and is of 2-course construction. It is 6½ in thick, 16 ft wide, built on crowned subgrade. During the week of Aug. 17, 1912, 7444 vehicles passed a given point on this road, and during the week of Sept. 18, 1912, 7580 vehicles, by actual count, passed the same point, which is near where the road was resurfaced. To better accommodate increased traffic, the road was widened to 20 ft.

Method of Reconstruction. "All the Tarvia surfacing and filling used to cover cracks was removed. The cracks and holes were then filled with concrete to make an even surface 20 ft wide. The expansion joints, as steel protection plates were not used, were mostly worn down. Where the joint was spalled to a considerable extent, the old concrete was broken away sufficiently to give a bond for new concrete on both sides of the joint. Expansion felt was then placed and the whole surface brought up to an even grade. On the top layer of this base was placed a 3-in layer of 1:1½:2½ concrete using Marquette, Mich., trap rock, graded in size from ¼ to 1 in for the coarse aggregate, and washed and screened bank sand for the fine aggregate. The surface in no place is less than 3 in thick, reinforced with No. 26 triangular-mesh wire. No endeavor was made to bond the top course to the old road with a rigid bond. The surface of the old concrete was first sprinkled with water, after which a mixture of Tarvia A and Tarvia X was sprinkled on, hot, with an ordinary sprinkling can, immediately before placing the new wearing surface. The Tarvia, falling on the moist concrete, spread in a very thin layer and was immediately chilled, thus forming an even coat over the old surface. The expansion joints in this top course coincide exactly with the expansion joints in the bottom course. A piece of wood, 3 by 4 in, 20 ft long, was laid over the old joint, and the concrete deposited as tho no joint were to be made. Afterward this piece of wood was removed, and armor plates suspended from installing bars, with expansion felt, were set into place on the side forms, the felt of the new joint meeting the tar paper of the base joint.

"It is wise to add a word of caution that this resurfacing is regarded as wholly in the nature of an experiment which should be watched and studied, rather than generally advocated, until it has proven itself out."

20. Maintenance Cost Data

The Long Run Costs include the interest or sinking fund demands based on the first cost, the charges for maintenance or upkeep, the cost of repairs and allowances for depreciation or obsolescence. Trustworthy information from widely dispersed sources concerning the detailed costs of upkeep and repairs on concrete pavements for a sufficiently long period has not yet been published. In the few cases, where detailed information has seemed to be accurately given, the statements have been lacking in other vital respects such as concerning the amount of use to which the particular road has been subjected. Manifestly, under such conditions, conclusions of value are impossible. Inskeep (40) states that the cost of repairs to about 7300 sq yds of concrete pavement built around a public square in Bellefontaine, Ohio, in 1893 and 1894, "under the existing conditions * * * in he last seven years has been $173.88." Much information of value in this connection is lacking, especially as regards the amount of traffic using the roadway. See (50g). Tentative deductions may sometimes be made, which will indicate possibilities, tho generally even these require assumptions from more or less controversial starting points and these assumptions may vitiate the results. For publications of figures on cost of maintenance of concrete roads, see (56) and (57).

Connecticut Method of Maintenance (64). "A straight well-made joint can be much more easily taken care of than any ragged crack which might result if no joint were used, or if the distance between were lengthened. All joints are treated with tar during the hot weather of the first summer after the completion of the work, and as often thereafter as necessary, but only in warm weather. A tar kettle of about 150 gal capacity, a pouring pot of the type use for pouring bituminous filler for brick pave-

ments, a wire push broom and a couple of laborers, comprise the outfit necessary to properly take care of this work. The joint is first brushed clean, then filled with tar and covered lightly with sand or stone chips, which have previously been distributed along the road. The cost of this work varies with the conditions of the joints and price of labor. Longitudinal cracks are the most frequent and annoying results of forces exerted after the work has been completed. These occurred more frequently on the earlier contracts which were not reinforced, and also on those which were so situated that the frost could effect an entrance under the road from the sides, lifting each edge and causing cracks to appear when the surface returned to its normal position. These cracks have been treated in exactly the same manner as the joints.

"Practically all of the work on the surface of these roads is performed in the same manner as outlined for tarring joints, and with the use of the same materials. A medium heavy tar which required heating is used. Any tar which will conform to the following specifications will be found satisfactory. Specific gravity at 21° C (70° F), 1.20 to 1.30. Free carbon, 10 to 25%. Distillation: Total to 77° C (170° F), not over 5%; total to 157° C (315° F), not over 30%. Specific gravity of entire distillation at 15.5° C (60° F), 1.033 to 1.038. Melting point of residue, 46° to 71° C (115° to 160° F).

"The size of the sand or fine stone used with the tar should depend on the size of the defect being treated, and should be clean. If defects are treated as soon as they appear, practically no cover will be used larger than torpedo sand.

"Actual COSTS of the maintenance for the various contracts have been kept for a period of 2 years, and the results are very satisfactory. Twenty-five miles of road have been used in obtaining the figures given care being used to include those carrying all classes of traffic from the heaviest to the lightest. The actual cost of all tar work applied to the concrete surface has been $38.63 per mile per year, or about 0.4 cents per sq yd of travelled path per year. The cost of shoulder work and drainage has been $28 per mile per year, or 0.3 cents per sq yd per year."

Maintenance Costs in Illinois (52b). "The average cost of maintenance and upkeep of concrete paved streets and roads in Illinois in 1915 was 0.4 cents per sq yd. This figure is the average for 75.3 miles of state aid highway, aggregating 555 013 sq yd of paved surface. The average cost of maintenance for 6.06 miles, 56 554 sq yd of pavement, on township aid concrete roads in 1915 was 0.81 cents per sq yd."

Table IX.—Maintenance Cost of Concrete Pavements in Illinois in 1915

County	Date of Acceptance	Labor	Material	Transportation	Equipment	Supervision and Overhead	Cost of Maintenance	Cost per Sq Yd
Adams	1915	$23.65	$14.86	$3.65	$5.35	$5.76	$53.27	$0.0059

SECTION 22

STREET CLEANING, COLLECTION AND DISPOSAL OF WASTE, SNOW REMOVAL

BY

WILLIAM H. CONNELL

ENGINEERING EXECUTIVE, DAY AND ZIMMERMANN, PHILADELPHIA

STREET CLEANING

1. General Considerations Relative to Street Cleaning

Engineering and Economic Problem. Street cleaning is one of the last municipal engineering problems to be placed under the control of engineers, and, in fact, it is in only a very few localities (1918) that this very important municipal service is under engineering control, as it is still being used in many localities for the purposes of political patronage. The principal factors in connection with this problem so far as cleaning the streets themselves is concerned are engineering and economic considerations. Engineering considerations embrace sanitary conditions, character and extent of traffic, character and condition of the pavements, social and local condi-

tions, and equipment and methods of cleaning, while the economic consideration resolves itself into a question of financial policy in each community. In other words, in this work as well as in paving work and all other public service work each community must determine upon its own policy. This does not mean, however, that sufficient cleaning should not be performed to comply with the sanitary requirements. It is for the engineer to determine upon the methods and the extent of the cleaning it would be desirable to do in order to keep the streets in as near as is possible an ideal condition from the standpoint of cleanliness, but, as in other undertakings, the prohibitive cost often makes it impracticable to attain the ideal.

Classification of Methods of Street Cleaning. In general two kinds of street cleaning are recognized, namely, preventive street cleaning and corrective street cleaning. Preventive street cleaning may be stated to consist principally in the institution and adoption of means of preventing dirt or waste materials being placed or scattered upon the highways; while corrective street cleaning consists in the collection and removal of such dirt or waste material as has found its way onto the highways. The responsibility for the performance of preventive and corrective street cleaning, it is recognized, must rest to a great extent, respectively with the general public, the municipal street cleaning organization and the police department. The police department is the only agency thru which the enforcement of the preventive street cleaning laws can be carried out, and the enforcement of these laws is essential in order that a solution of the street cleaning problem may be effected.

2. Preventive Street Cleaning

General Considerations. Tho the results accruing from the activities included under preventive street cleaning cannot be definitely expressed in figures, as in the case of corrective street cleaning, it is, however, just as important a function of street cleaning as the performance of the corrective work itself and every effort exerted in this direction is fully justified. For obvious reasons, it is absolutely certain that preventive methods are destined to enter more and more into the street cleaning problem in every municipality. In formulating a definite policy along which preventive street cleaning work should be conducted, it is necessary first to determine the contributing causes to unclean streets, in order that it may be possible to control or eliminate them thru carefulness, thoughtfulness, or observance of the laws on the part of the general public.

Principal Causes of Unclean Streets.

1. The neglect of occupants of homes, stores and other buildings to properly dispose of sweepings and refuse from their premises and sidewalks, and to refrain from sweeping or placing such materials onto the highways, especially after they have been cleaned.

2. The failure to use tight metal or other suitable receptacles for ashes, rubbish and garbage; the failure to allow a clear space of several inches between the tops of the receptacles and the top of the contained materials in order to prevent their being blown or spilled upon the highways; and the lack of care in the manner of storing receptacles while awaiting collection, so as to prevent their being overturned by passing traffic.

3. The illegal and careless distribution on the highways or to homes and other buildings of advertising literature in the form of circulars, handbills, cards and fake newspapers.

4. The neglect of pedestrians to properly dispose of discarded newspapers, cardboard boxes, paper, fruit peelings and refuse.

5. The non-separation by occupants of homes and other buildings, of rubbish from ashes, placed on the highways for collection by the municipal collectors.

6. The interference with and scattering of the contents of receptacles awaiting collection, by itinerant scavengers.

7. The overloading or improper loading of vehicles hauling dirt or other fragmentary materials, or the use of defective or unsuitable conveyances; and the permission of vehicles entering upon the highways with the wheels carrying an accumulation of dirt or mud.

8. The illegal and careless packing, unpacking or storage of materials on the highways.

Enforcement of Preventive Measures. In order to eliminate or reduce to a minimum these contributing causes, every effort should be made to educate the general public in their individual duties, and to the necessity, advantages and possibilities of preventive street cleaning. Insofar as it is practicable and possible for the city to do so, equipment and helpful suggestions and instructions should also be furnished.

The Principal Specific Means for Controlling These Causes Employed by the Philadelphia Bureau of Highways, 1912 to 1917, may be enumerated as follows:

1. Continuous educational work consisting of extensive newspaper publicity, public neighborhood lectures; and, where practicable or necessary, individual personal advice or instruction from the inspectors.

2. The inauguration of an intensive educational preventive Clean Streets Campaign under the joint auspices of the City of Philadelphia, The Philadelphia Chamber of Commerce, the United Business Men's Association, the Poor Richard (Advertising) Club, the Philadelphia County Medical Society, the Child Federation, the Emergency Aid Association and the Civic Club of Philadelphia, for the purpose of enlisting the aid of every possible coöperating agency.

3. The personal serving by police, upon the responsible occupant of every home and other building thruout the City, of cards enumerating in the form of Don'ts the most generally prevailing violations of the laws which contribute toward unclean streets, together with abstracts of the laws and the penalties for their violation; and the exhibition of displayed placards containing this data in the trolley cars, store windows, railway stations and other conspicuous places thruout the City.

4. The assignment of specially trained forces of inspectors to personally appeal to occupants of homes and other buildings to coöperate by obeying the existing laws.

5. The sending of legal notification letters to persons or agencies who persisted after warning, in violating the laws in matters contributing to unclean streets, and prosecuting the offender in instances where further violations are noted.

6. The assignment of an assistant engineer to enlist and encourage the coöperation of housekeepers and school children by giving informal talks at schools and before women's organizations.

7. The furnishing and maintenance of attractive rubbish receptacles in prominent locations on the highways thruout the City; and the encouragement of large business interests and civic, and neighborhood business men's and improvement associations to assist in the extension of this work.

8. The general enforcement of the municipal ordinance requiring the separation of ashes and rubbish.

9. The enforcement of the law requiring occupants of homes and other buildings to provide approved types of rubbish and garbage receptacles, and to properly store them while awaiting collection.

10. The control, thru the coöperation of the police department, of itinerant scavengers operating in violation of the law, with a view to their ultimate elimination.

11. The institution of an annual Clean-Up Week, which insures the periodic and satisfactory disposal of a very considerable quantity of rubbish, a proportion of which would otherwise ultimately find its way onto the highways.

12. A closer attention to the character and suitability of the vehicles employed and the manner of loading and transporting dirt and other fragmentary materials over the highways, and the assignment of an inspector where necessary to inspect such vehicles prior to permitting them to enter upon the highways.

Publicity. In connection with the preventive street cleaning propaganda, it is considered that publicity of the kind that will reach and favorably impress the entire body of citizens is absolutely essential to the attainment of results. In this connection, publicity is obtained thru the following mediums:

NEWSPAPERS. New items in both daily newspapers and weekly neighborhood periodicals relating to the day to day activities of the bureau of highways in connection with the preventive street cleaning work and also stories of the experiences and conditions discovered by the educational inspection force.

MEETINGS. Public meetings held under either the specific or joint auspices of the municipal government, civic and trade bodies and neighborhood business men's and improvement associations.

LITERATURE. Educational notice cards and pamphlets describing the various ways in which householders and citizens in general may coöperate; placards for store window, trolley car, railway station and bulletin board display and poster stamps for attachment to correspondence and bills sent to the public by the municipal government, public utilities and business houses.

Clean-Up Week. The main purpose in conducting an annual municipal clean-up week campaign is to provide healthier and safer living conditions for the people in general by removing accumulated trash and rubbish from the interior of buildings and from all open areas. It is a demonstrated fact that carelessness in the storage of rubbish in cellars, attics and closets is responsible for a considerable portion of fire losses, while it has also been shown that unclean surroundings breed disease germs, which are in turn transmitted to human beings thru various agencies. To clean up regularly by collecting and disposing of all useless trash gives to a community an orderly and well-regulated appearance and eliminates much rubbish that would in all probability contribute at some later time to the littering of the highways. It stimulates the citizens, whether rich or poor, to concentrated effort at stated times and thereby develops instinctively the habit of cleanliness and orderliness. To promote such a campaign successfully requires the active coöperation of every individual in the municipality. Obviously, the necessary information covering the general plan of procedure must first be given to each man, woman and child and in a form to be assimilated by each. It must also be repeated as often as necessary in order that each one may be impressed with his or her personal responsibility in the matter. Publicity, therefore, should be the key-note of a clean-up campaign. The best results will be obtained thru a joint working committee of city officials and members of the local Chamber of Commerce or Board of Trade, their principal objective being to start the campaign and keep it in motion by using every available channel of publication. The newspapers are possibly the most efficient mediums of publicity and by publishing daily news articles, advertising wares of tradesmen and in giving ample advance notice of the coming event, keep the idea constantly in the public eye. The assistance of the local public service corporations in the preliminaries of the campaign by placing placards containing information in trolley cars and stations and by using poster stamps on bill heads, statements and outgoing mail is invaluable; business men's and civic organizations thru conducting neighborhood meetings and distributing literature gain the attention of the people living in their immediate vicinities; children in public and private schools thru a course of instruction as to the part they may take in cleaning up, which also provides for the awarding of prizes for the best appearing yards, alleys, etc, are encouraged to individual effort; inspection of divided areas of the municipality by Boy Scouts and other junior organizations in order to locate vacant lots, open areas, yards, alleys, etc, requiring the attention of the owners is a most important feature. The campaign should be officially begun by the mayor issuing a proclamation just prior to the opening of clean-up week requesting all citizens to give their best efforts to one week of cleaning up and beautifying.

OPERATIONS DURING CLEAN-UP WEEK. The preliminary or educational features of the campaign having been thoroly coördinated and properly concluded, the actual work of collecting and disposing of the waste materials set out, requires rapid and efficient handling on the part of the organization in charge. In a large municipality, particu-

larly during the first and second campaigns, an increase of not less than 25% in the number of extra teams employed over the number usually required to collect rubbish will be necessary with a corresponding increase in the number of helpers, in order to complete each day's work according to the department schedule. As the disarrangement of the schedule of an ash and rubbish collection and street cleaning department is serious, every effort should be made to complete the clean-up campaign within the prescribed time. This, of course, requires judgment in the employment of additional equipment and helpers for which no set rule can be formulated. It will depend entirely upon the arrangement of the daily schedules, ample provision being made beforehand for those districts in which the normal weekly collections are heaviest.

Results Obtained. The best results are not to be looked for during the first campaign as the public in the beginning may be more or less apathetic and incredulous but they will be quickly converted to the value of the idea once the impression is gained that it means safety against disease and fire. Thereafter, cleaning-up gradually becomes habitual with the real purpose of the movement, which is to encourage continuous or year-round cleaning constantly progressing. The successful results of such a campaign may be summarized briefly as follows:

1. Reduction in fire loss and elimination of fire hazards; the lessening of the number of house flies and mosquitoes during the summer months.

2. The improvement of sanitary conditions and the elimination of objectionable conditions on vacant lots; cleaner houses, yards and alleys, safer and more attractive houses and surroundings.

3. The training of school children in the principle of the cleaning up idea; fire prevention, cleaner streets, development of school and neighborhood gardens, etc.

4. A higher standard of civic pride in the people for their city.

Philadelphia Clean-Up Campaigns. This procedure has been followed in Philadelphia most successfully from 1913 to 1916, inclusive, the administration of the campaign and the collection and removal work being under the auspices of the Bureau of Highways and Street Cleaning, which is in responsible charge of the collection and disposal of ashes and rubbish. Tho the other branches of the municipal government, such as the Departments of Health, Police and Fire, should coöperate in the campaign, yet the department having regular charge of rubbish collection thruout the year is the logical organization to supervise the clean-up week campaign. During the Philadelphia campaigns of 1913 and 1914, the accumulations were noticeable for the presence of heavy and cumbersome articles, such as furniture, bed springs and mattresses, etc. In 1915 and 1916, minor household waste and refuse, such as discarded tin and iron ware, kitchen utensils, rags and carpets, broken china ware, glass and bottles, predominated. The difference in the character of materials collected and transported to the City dumps during these years represents the improvement in general conditions within homes and may be regarded as a typical experience, which any municipality about to conduct a clean-up campaign may expect. In 4 years, rubbish and waste to the amount of 388 000 cu yd was collected and disposed of during Clean-Up Week at a total cost to the City of $61 400.72, or an average of 15.8 cents per cu yd, or $0.0361 per capita. During each campaign, an average of 1500 extra teams and 225 extra helpers were employed in the work of collecting and transporting waste to the reclamation stations and other rubbish, not of a salvable nature, to the dumps.

Highway Rubbish Receptacles. In order to encourage pedestrians to properly dispose of discarded newspapers, card board boxes, fruit skins and other refuse and to provide convenient facilities therefor, specially designed portable highway rubbish receptacles should be placed at highway intersections and in front of schools, factories, railway stations and at other conspicuous locations on the highways, thruout the city and also on the streets occupied by curb produce markets. These receptacles are durably manufactured of sheet and strap iron and are cylindrical in shape with half-hooded top and a drained and ventilated bottom. They have a capacity of 5.4 cu ft. Eight stiffening staves on the outer side of the receptacle extend from top to bottom at equi-distant points, and two handles are placed at the middle on opposite sides of the receptacles. The receptacles may be painted grass green and contain in white, the wording "For Waste Paper and Refuse. Help Keep the Streets Clean." A number of the public utilities, large business houses and neighborhood business men's and improvement associations may provide, at private expense, a number of

similar receptacles for use in their vicinities. The contents of all highway rubbish receptacles should be collected daily by the rubbish collection contractors.

3. Corrective Street Cleaning

Frequency Classifications of Street Cleaning. In general, frequency and sequence of street cleaning is based upon considerations of economy and actual necessity as governed by sanitary considerations, the character and condition of the pavement, the volume and character of the traffic, the locality and the convenience of the traveling public.

In Philadelphia, from 1912 to 1917 while the author was Chief of the Bureau of Highways and Street Cleaning, the following system of classification was utilized, each class to be cleaned according to a definite prearranged schedule.

City Streets:

Class A. Cleaned every day, meaning each day except Sun. or the legal holidays as indicated in the specifications.

Class B. Cleaned every second day, meaning Mon., Wed. and Fri.; or, Tues., Thur. and Sat. of each week.

Class C. Cleaned every third day, meaning Mon. and Thurs.; or, Tues. and Fri.; or, Wed. and Sat.; or, Mon. and Fri.; or, Tues. and Sat. of each week.

Suburban and Country Roads.

Class D. Cleaned once a week on a definite day.

Class E. Cleaned twice a month.

Class F. Cleaned once a month.

Class G. Cleaned once in 6 weeks.

Class H. Cleaned once in 2 months.

Methods of Street Cleaning in General Use. In determining upon the method of cleaning to be employed upon any specific highway, the first consideration is that of the character and condition of the pavement to be cleaned, but, in addition to this, sanitary, traffic, public convenience and economic considerations play an important part. The general methods at present employed in the cleaning of pavements and roads are as follows: (1) Pick-up by blockmen; (2) machine broom preceded by sprinkling; (3) squeegee preceded by sprinkling; (4) high pressure machine flushing; (5) hand brooming by gangmen; (6) hose flushing. Tho in the organization of the machine cleaning practice an effort has been made to standardize the methods of cleaning with respect to character of pavement and other governing conditions, it is nevertheless quite impossible to adhere strictly to the standards determined upon during freezing weather which frequently necessitates radical departures. Squeegee and flusher cleaning and sprinkling is discontinued when a low temperature makes their use undesirable. When, however, on account of weather or temperature conditions, squeegee or flusher cleaning or sprinkling must be discontinued and machine brooms cannot be operated, the streets are cleaned by supplementing the regular force of blockmen with additional gangmen and the regular force of laborers, alley and inlet men.

Machine Broom Cleaning. Machine broom cleaning is used principally on stone and vitrified block or brick pavements, and also on sheet-asphalt and wood block pavements having a rough or irregular surface. It is practically impossible to have absolutely clean streets unless they are well paved. The older types of stone block and brick pavements constructed without grouted joints are difficult to clean, as dirt lodges in the joints, especially if they are wide. Pavements not laid on a concrete base will, in all probability, develop numerous depressions due to settlement under

the severe requirements of traffic. These depressions, of course, collect dirt, much of which cannot be removed by the machine broom and has to be broomed out by hand.

Method. The machine broom gang unit should consist of a horse-drawn sprinkler followed by a battery of 1, 2 or 3 horse-drawn machine brooms, the number depending upon the width of the street to be cleaned, 1 foreman and from 4 to 8 gangmen should follow each machine broom, depending upon the character and condition of the pavement and the quantity of dirt to be removed, and from 4 to 8 carts with drivers and helpers if necessary. All laborers should be equipped with push brooms. In working the machine broom gang, it should be so arranged that the various operations will be performed closely following one another. The sprinkler should precede the machine brooms by about 200 ft. The output of water from the sprinkler should be so regulated that just enough is used to loosen the dirt and to prevent the formation of dust during the sweeping operations. If an excess of water is used, the dirt becomes pasty with the result that the machine broom cannot properly clean the pavement. The machine brooms, in battery formation, should follow 200 ft in the rear of the sprinkler, and the dirt should be swept from the center of the roadway toward the gutters. The foremost machine broom should progress along the center line of the roadway, closely followed by the other brooms, each of which should overlap the swath of the preceding broom to pick up the windrow of dirt collected by that machine, thus finally conveying it to the gutter. Tho the brooms in the machines are usually from 6½ to 8 ft in length, yet the actual width of the cleaning swath will not exceed between 5 to 7 ft, due to the angle at which the broom is set in the machine and to the fact that where more than one swath is necessary to clean a roadway, each successive swath must overlap the preceding one. If the machine brooms are in good condition and properly adjusted only one operation will be necessary to clean a pavement satisfactorily but where the pavement is in bad condition or the roadway is unusually dirty, it may be necessary to go over the roadway two or more times or resort to flusher cleaning. If the condition of the roadway with respect to dirt is such that the pavement cannot be satisfactorily cleaned in one operation, it is advisable that the street should be scheduled for more frequent cleaning. All areas or depressions which the machine brooms cannot properly clean should be carefully spot cleaned by gangmen. The gangmen should follow close behind the machine brooms, and in no case more than 400 ft, brooming the dirt into piles in the gutters at intervals of about 25 ft. The dirt collection vehicles should closely follow the gangmen and the piled dirt should be immediately loaded into the vehicles and hauled to the dump. The important reason for keeping the gangmen and dirt collection vehicles working close behind the machine brooms is to prevent the dirt from being scattered by traffic and wind. If too great an interval is allowed between the brooms and the gangmen, the dirt will become dry, especially in hot weather, and when the gangmen broom the dirt into piles, considerable dust will be raised. Dust is not only unsanitary, but also is very annoying to passing pedestrians and the occupants of near by buildings, and, therefore, every precaution should be taken to eliminate this nuisance. The dirt should be piled in the gutters where neither the dirt nor the vehicles collecting it are in the way of moving traffic. After the dirt has been loaded into the collection vehicles any dirt left on the site of the pile should be carefully broomed with a small handbroom into a shovel and the site left perfectly

clean. A properly adjusted and equipped machine broom will satisfactorily clean an average of 90 000 sq yd of pavement per day of 10 working hr. This area will, of course, vary somewhat, depending upon local conditions, such as the character and condition of the pavement and the amount of traffic.

Squeegee Machine Cleaning. Squeegee machine cleaning is confined exclusively to sheet-asphalt, bituminous and wood block and brick pavements having a smooth surface. If these pavements are not in good condition, or contain depressions or pot-holes, satisfactory results cannot be obtained by using this type of equipment. Another point to be considered is that squeegees will not satisfactorily clean a pavement that is very dirty or one that is not cleaned at frequent intervals. Squeegee cleaning is intended primarily for roadways where the dirt to be removed is comparatively light, either because they are patrolled by blockmen or the traffic does not produce an excessive quantity of dirt.

Method. The squeegee gang unit should consist of a horse-drawn sprinkler followed by a battery of 1, 2 or 3 horse-drawn squeegee machines, the number depending upon the width of the roadway to be cleaned, 1 foreman and 3 gangmen to each squeegee machine and 2 or more dirt collection vehicles with drivers. All gangmen should be equipped with push brooms. In operating, the squeegee machine gang should be so arranged that the various parts of the gang will work together as closely as practicable. The sprinkler should precede the squeegee machines by about 200 yd. This interval of space is sufficient to permit the water to saturate and loosen up the dirt on the pavement without giving it time to evaporate. Squeegee machine cleaning requires the application of considerable water to the pavement surface and sufficiently in advance of the rubber brooming operation to loosen the dirt thoroly. The squeegee machines, in battery formation, should follow 200 yd in the rear of the sprinkler, and the dirt should be broomed from the center of the roadway toward the gutters. The foremost squeegee machine should progress along the center line of the roadway, closely followed by the other squeegee machines, each of which should sufficiently overlap the swath of the preceding machine to engage the windrow of dirt collected by that machine thus finally conveying it to the gutter. Tho the rubber brooms in the squeegee machines are usually from 7 to 7½ ft in length, yet the actual width of the cleaning swath will not exceed 6 ft, due to the angle at which the broom is set in the machine and to the fact that where more than one swath is necessary to clean a roadway, each successive swath must overlap the preceding one. In every case a sufficient number of swaths should be taken to cover completely the entire width of the pavement and to convey the windrows close to the curbs. If the squeegee machines are in good condition and properly adjusted only one operation will be necessary to clean a pavement satisfactorily but where the pavement is unusually dirty, it may be necessary to go over the roadway two or more times. All depressions which the squeegee machine cannot properly clean should be carefully spot cleaned by gangmen. The method of procedure for the removal of dirt should be identical with the requirements outlined in connection with machine broom cleaning. A properly adjusted and equipped squeegee machine will satisfactorily clean an average of 75 000 sq yd of pavement per day of 10 working hr. This area will, of course, vary somewhat depending upon local conditions.

High-Pressure Flusher Machine Cleaning. High-pressure flusher cleaning may be satisfactorily used on practically all types of pavements. In some cases, it supplements the other methods of regularly scheduled ma-

chine cleaning. It is very effective on all kinds of stone and vitrified block or brick pavements and on sheet-asphalt and wood block pavements where the surface is so worn or irregular that the depressions would hold dirt that could not be dislodged by either squeegee or machine broom cleaning. The principle upon which the high-pressure flusher method of cleaning is based is that of loosening the dirt from the pavement surface by jets of water under pressure and then flushing the dirt to the gutters.

Method. The flusher cleaning gang unit should consist of one or more automobile high-pressure flushers with a driver and 1 operator each, 1 foreman, from 4 to 6 gangmen and from 1 to 3 dirt collection vehicles and drivers. The correct position for the flusher nozzles is the most important consideration in this kind of cleaning. They should be set approximately 18 in above the pavement surface and set at such angles as will insure a thoro cleaning of a maximum width of pavement. The front nozzle streams should form windrows in such positions that the rear nozzle streams can pick up and throw them toward the curbs. The streams from the two front nozzles should cross, but not cut thru each other, as this will diminish the force with which the water strikes the pavement. Each nozzle should have an effective swath of 8 ft in width on smooth pavements and of 6 ft in width on irregular or block pavements. After the correct positions for the nozzles have been finally determined, they should be permanently locked or set in those positions; otherwise, they will be constantly tampered with by the foremen and others, and very poor cleaning will result. The pressure under which the water is ejected from the nozzles also should be given careful study. The usual pressure is 40 lb per sq in. When the flusher is operated on narrow roadways that can be cleaned by one swath, or on other roadways where the pavement is very dirty or is of an open joint block type, the rate of progress should not exceed 3 to 4 miles per hr. On smooth-surfaced or comparatively clean pavements the speed may be relatively increased, but should not in any instance exceed 8 miles per hr. The general tendency on the part of flusher operators is to go too fast. This will result in poor cleaning especially if the pavement is comparatively dirty. The matter of proper speeds for flushers should be given careful consideration and standard regulations adopted to suit the several varying conditions. On streets requiring more than one swath to clean them, the first swath should be taken along the center line of the street and a sufficient number of successive overlapping swaths made to carry the windrows to the curbs. When operated in conjunction with squeegees, the flusher should progress along the center of the roadway with the squeegees following in battery formation. Enough gangmen should closely follow each flusher or battery to broom the dirt along the gutters to the nearest sewer inlets, where the dirt is piled and the water allowed to drain into the sewer. The flusher may be operated either up or down grade, but the gangmen must always work down-grade. The dirt collection vehicles should closely follow the gangmen and load and haul the dirt to the dump. All dirt sites should be left clean by brooming up any remaining dirt. A high pressure flusher should satisfactorily clean 100 000 sq yd of pavement in a day of 10 working hr. The percentage of time that the machine will consume in loading water will vary greatly with the pressure at the hydrant.

Hose Flushing. The hose flushing method of street cleaning can be made use of readily by a city of any size, as it has the great advantage of not requiring an expensive equipment. This method is of special value for quick and thoro clean-up work and for removing entirely the dust from

the surface of city streets. As a rule, however, hose flushing in the larger cities supplements rather than replaces machine cleaning, except on roadways too narrow to permit the use of the machine cleaning equipment. The principal disadvantage of hose flushing is that of the waste of water unless the work is closely supervised. In order to accomplish effective results with hose flushing, the hose stream should be kept in motion at all times and directed downward on the surface of the pavement within a radius of 40 ft of the nozzle man. If the hose stream is directed at one spot more than 20 or 30 sec, this generally results in a waste of water and time. In no case should the hose stream be raised upward into the air as this results in the pavement being simply sprinkled rather than washed.

Methods. There are two general methods of hose flushing, which may be described respectively as the large gang method and the small gang method.

In the large gang method, the flushing gang unit should consist of 1 foreman and 8 laborers, equipped with not less than 150 ft of 2 or 2½-in hose, a portable hose reel, push brooms and, if necessary, hoes and shovels. The hose should be provided with an elliptical nozzle, made purposely for this class of work. The method of operating this gang is, first, to have the pavement thoroly wetted; any pavement area that cannot be reached by the hose stream should be wetted by brooming water over it, the idea being to moisten and loosen the dirt. The broom men then form in battery and proceed down grade, while the hose men play a stream of water in front of them. The windrows from the first and other brooms are engaged successively by the brooms following and are carried finally to the gutters. If necessary, in order to produce satisfactory results, this operation should be repeated two or more times. When conditions warrant it, 2 or more men also may be assigned to spot flushing and cleaning. A hose flushing gang should clean, in a satisfactory manner, 30 000 to 35 000 sq yd of pavement in a day of 10 working hr.

In the small gang method of hose flushing, the gang unit should consist of 2 men, and all the dirt must be removed by the water. The flushing is done down grade and the mud wave is driven toward the gutters.

Report on Investigation of Hose Flushing by Parlin (32). "Until 1914 New York City had been using ordinary 2½-in fire hose and 1¼-in nozzles. The equipment was carried on the regular sweeper's can carrier or dragged over the pavement from place to place by 2 or 3 sweepers. This equipment was not only ill-adapted to the work but heavy, unsightly and liable to cause rapid deterioration of the hose on account of the sharp bends which were necessary.

"Investigations made by Wagner, an engineer from the Dept. of Water Supply, Gas and Electricity, New York City, indicated that:

1. An average of 1800 gal of water was being used per 1000 sq yd of pavement cleaned.
2. Other cities were using smaller sizes of hose and nozzles with apparent satisfaction.
3. Experiments made with 1½-in and 2-in hose and small nozzles indicated that the work of cleaning could be properly done with from 370 to 660 gal per 1000 sq yd on asphalt.

"As a result it was recommended by the engineer that the department of street cleaning adopt 1½-in equipment, which would be much easier to handle and save more than two-thirds of the water then used. The recommendation did not agree with the experience of the officers of the department of street cleaning, several of whom had tried the small equipment. The claim was almost universally made among these men that the use of so small a hose and nozzle would make it impossible for men to cover the ground they were then covering and would make the work very expensive. Thus developed two points of view, one looking primarily at the waste of water and the other at the waste of time. Between these it became necessary to run a second set of experiments to determine the size of equipment which would be cheapest to

operate from the taxpayers' or general city view-point, taking into account both the cost of labor and the cost of water. This second set of experiments, conducted alternately upon 1½-in and 2-in equipment, resulted in the selection of the 2-in equipment as standard for the city. Attention was at the same time called to the possibility of using the smaller size with equally good results wherever the pressures at the hydrants were in excess of 50 lb per sq in.

"As a result of these and further experiments the following general principles appear to be established.

1. That the economical size of equipment is dependent upon the hydrant pressures available and the length of hose used.

2. That when the pressure at the nozzle is in excess of 25 lb per sq in, water is delivered thru a ¾-in nozzle faster than it can be properly used by 2 men, and that it is accompanied by excessive splashing.

3. That when the pressure at the nozzle is less than 18 lb per sq in, water is not delivered fast enough to keep up with the men nor with force enough to enable them to do effective work.

4. That the smallest size hose which will give pressures at the nozzle between 18 and 25 lb is the most economical for use.

5. That the better results can be secured by spraying ahead as far as the stream will reach, to give the material on the street a preliminary soaking prior to the direct flushing, than can be secured by the direct flushing of a dry pavement.

6. That larger quantities of water are required to clean rough pavement than smooth, and therefore a slightly larger nozzle may be used to advantage. It is estimated that a ¾-in will be satisfactory for asphalt and a 1-in for rough Belgian block.

7. That shut-off nozzles are necessary whenever working in traffic, both to save water and to prevent accidents.

8. That where water mains are large enough for proper domestic and fire supply, flushing will not interfere with the ordinary household use.

9. That a hose reel will enable the gangs to do more work with the same expenditure of energy and at the same time lengthen the life of the hose.

10. That by the adoption of procedure which prevents any back tracking of the equipment, over 4 miles of walking can be saved per gang per 8-hr day in covering a given amount of street, as compared with the procedure commonly used in the past, which saving enables the gangs to do more work.

"As a result of the studies and conclusions reached, a new hose reel, new hydrant equipment and improved procedure were adopted by the department and put into effect. The procedure may be outlined as starting with the hose reeled with the nozzle on top, commencing to unreel when at a distance equal to the length of the hose from the hydrant, unreeling toward the hydrant, placing the reel on the sidewalk near the hydrant, flushing from the point nearest the nozzle past the hydrant and as far as the hose will reach beyond the hydrant toward the nozzle, thus completing the area served by a single hydrant. Whenever moving hose, the hydrant man is required to pick it up in loops and drag it ahead in such a way that it will not cross other loops, and he is expected to keep a loop at the nozzle end, even with or slightly ahead of the nozzle man so that the latter will be free to move without assistance at all times.

"While previous to the adoption of the new methods and procedure it was seldom possible to flush effectively much over 25 000 sq yd of pavement per day, it is common now for a 2-man gang to cover from 30 000 to 45 000 sq yd in an 8-hr day, making as many as 45 or 50 connections to the hydrants. This means unit costs for labor and equipment of 11.9 to 17.8 cents per 1000 sq yd. The first cost of the equipment is approximately as follows:

Three 50-ft lengths 2-in rubber hose* at 54 cents	$81.00
One ¾-in shut-off nozzle	7.00
One 2½-in to 2-in reducer, hand swivel type	2.25
One hydrant key	0.11
One hose reel	30.00
	$120.36

*Rubber covered hose is preferable to cotton jacket hose for his work."

Note: The above costs appear to be exclusive of water and removal of dirt, and of course a 2-man gang can not clean as thoroly a dirty business street as a larger

gang brooming the entire area of the pavement behind the stream of water. The costs given for the gang method are 45 cents per 1000 sq yd, Philadelphia and Washington.

Comparison of Machine and Hose Flushing. Of the methods of street cleaning in general use the hose is unquestionably the most efficient. In machine cleaning the rate of speed thru the entire width and length of the street is the same. It is obvious that some sections of the pavement require more effort to entirely remove the dirt which has a tendency to stick to the pavement than they ordinarily receive in the regular process of machine cleaning. In the hose method of flushing pavements where such a condition represents itself the hose is pointed on this area of the pavement until the dirt is entirely removed, and likewise a less amount of water and effort is used to clean the sections of pavement that are comparatively clean. In the machine method of flushing the same quantity of water and the same pressure is exerted on the entire area of pavement, irrespective of the amount of cleaning required. It is a fact, however, that the hose flushing of business streets carrying a considerable amount of traffic which constantly get rather dirty, is more expensive than the automobile flushing, but likewise it is more effective.

Blockmen Cleaning. Pick-up and spot cleaning by hand patrol blockmen is an auxiliary method of cleaning, and is intended only to supplement the regularly scheduled machine cleanings. This method of cleaning is confined principally to highways where the character and volume of the traffic and the nature of the surroundings make its use desirable or necessary in the interval between the regular machine cleanings. To each patrol blockman should regularly be assigned a definite area of highway pavement to be kept clean. This area may vary between 2 500 and 15 000 sq yd, depending entirely upon the specific conditions of requirements of each assignment. The equipment furnished to each blockman should consist of a portable bag or can carrier, one or more burlap or canvas bags or metal cans, a pan scraper, a push broom, a hand broom, a sprinkler can, and a fire hydrant key and reducer. The work performed by the blockmen should include picking up paper and other refuse which finds its way on to either the footway or the roadway and sweeping up and removing animal droppings and detritus as soon as possible after it accumulates in order to prevent its being scattered by wind or traffic. The material to be removed is either scooped up in the pan scraper or swept into a pile and then removed. Each blockman should be provided with a sprinkling can and should sprinkle the pavement before sweeping in all instances where the dust will annoy passing pedestrians. The blockmen should be required to place in the bag or can, which is mounted on the carrier, all dirt and other refuse or waste paper collected. These filled bags or cans should be promptly removed by collection vehicles which should call at regular intervals each day. Cleaning by patrol blockmen will produce very effective results if the work is performed under the supervision of competent foremen, otherwise there is a general tendency on the part of the men to shirk.

Experimental Vacuum Cleaners. The methods of cleaning that have been described in detail are only those in general use. For a number of years experiments have been carried on with vacuum cleaners, and as a matter of fact several types of vacuum cleaners are in use in some of the cities of the United States. The principal disadvantage of the regular vacuum cleaner is its inability to clean the streets in wet weather. This would make it impossible to use this type of machine in eastern cities during wet days in the summer and most of the winter months. A type of machine will in all probability eventually be in general use that will consist of a combination vacuum

cleaner and sweeper, so that it could remain in constant use on days when it rains after the cleaning equipment is at work. In Los Angeles and St. Louis there have been very extensive experiments carried on with the vacuum cleaner.

Alley Cleaning. From a sanitary standpoint, the cleaning of alleys is of particular importance, especially in the more thickly populated portions of a city and during the summer season. An alley cleaning gang unit should consist of 1 foreman, from 6 to 10 laborers, equipped with at least 150 ft $2\frac{1}{2}$-in hose with a nozzle, a portable hose reel and push brooms, and one or more water-tight metal dirt collection vehicles. Depending upon conditions, some alleys are flushed while others are cleaned by sweeping. In flushing an alley, the stream of water should be played as far up the alley as possible, and one or two gangmen beginning at the high point or end of the alley should sweep down grade toward its outlet. The dirt and rubbish swept out of the alley should be piled in the gutters of the roadway opposite the alley, removed at once and the site cleaned. If necessary, the alley should be flushed and swept a second time after the bulk of the dirt has been removed. If an alley is only swept, the work is performed in substantially the same manner as previously described. An alley cleaning gang should sweep and flush approximately from 30 000 to 50 000 sq yd of alley pavement in a day of 10 working hr.

Road Cleaning. Included in this category must be considered all highways with roadways of such materials as earth and water-bound broken stone and gravel. Due to the varying road conditions encountered practically all of the work must necessarily be performed in such a manner as may be required by the conditions existing on the specific road rather than in accordance with definitely prescribed methods of operation. However, in the more closely built-up portions of the suburban sections, the road cleaning work more nearly approaches in methods of operation, the work performed by gangmen on the city streets. The road cleaning work gang unit should consist of 1 foreman, 6 laborers, who are equipped with push brooms, shovels, picks, hoes, rakes and sewer inlet hooks and rakes, and one or more dirt collection vehicles. Due to the variety of the work performed by the road cleaning gangs it is not possible to indicate in concrete figures the amount of work that such a gang can do in a day.

Sewer Inlet or Catch Basin Cleaning. In order to insure the prompt disposal of all surface drainage and storm water, it is necessary that the traps of all sewer inlets be kept clear of obstructions or accumulations of muck. To provide for this, it is necessary that sewer inlets be periodically inspected and cleaned. On paved streets or roads, the sewer inlets should be cleaned at least once every 2 weeks, but if the inlet is adjacent to an unpaved street or is otherwise so located that dirt is liable to be washed into it, more frequent cleaning will be necessary. The sewer inlet cleaning gang unit should consist of one or two laborers and a dirt collection vehicle. The dirt can be loosened and lifted out of the sewer inlet by means of an inlet hook and an inlet rake, the latter of which consists of three flat parallel prongs about 10 in in length attached at right angles to a long handle. The removed dirt is piled in front of the inlet and promptly removed in water-tight and covered metal-bodied vehicles. If the pipe connection between the inlet and the sewer is obstructed, the water is baled out of the inlet trap and the inlet man after entering the inlet endeavors to remove the obstruction by hand. If not successful, a hose line from a fire hydrant is then inserted into the inlet connection and the dirt is forced thru the

connection into the sewer. If the obstruction is such that it will not yield to water pressure, it is necessary to make an excavation in the street or road and remove the choked section of pipe.

Cleaning Methods Dependent upon Type of Structure. The methods of construction of inlets and catch basins adopted in the different parts of the country have a certain bearing on the efficiency of cleaning. A type of inlet commonly used in a large eastern city is built partly under the sidewalk and partly under the roadway. It has the advantage of securing a much larger basin area and also does away with cast iron grates or cover plates in the roadway gutter, which are objectionable owing to the frequency with which they must be replaced on heavy traffic thorofares. In this type of inlet, a circular cover similar to an ordinary manhole cover is inserted in a large granite block set in the sidewalk directly over the basin. The catch basin is, therefore, cleaned from the sidewalk instead of the gutter, the principal objection being the uncertainty of thoroly cleaning that section of the basin lying outside of the trap-stone or under the roadway. It is also, to a limited extent, objectionable from a sanitary standpoint as, in the operation of cleaning, the removed muck very often gives the sidewalk a dirty appearance unless extreme care is taken. While the type of inlet referred to is heavier in construction, has greater capacity and is more economical in maintenance, the street inlet or catch basin is more universally used because of its greater adaptability to the needs of cleaning. Automatic or self-cleaning inlets do not have the trap feature. They are built with a large basin from which the dirt is directly transferred to the sewer thru a pipe connection, attached to the sewer at a steep angle. Such inlets are only practicable where the sewers are laid on a heavy grade, insuring the removal of all refuse and other materials due to increased volume and velocity of flow.

Mechanical Cleaning. A mechanical device, known as the hydraulic inlet cleaning machine, operates on the hydraulic pump principle. A metal body mounted on an automobile truck receives the muck direct thru a hose inserted in the inlet catch basin. A continual flow of water from the street plug to the inlet is maintained, while the cleaning operation is in progress. The contents of the inlet, dirt and water combined, are drawn upwards thru the hose, the pumping power being supplied by the automobile engine and extra gearing attached to the truck for the purpose. After depositing the contents of the inlet in the truck body, the heavier materials sink to the bottom and the excess water is released thru valves and is returned to the inlet. This process continues until no dirt remains in the bottom of the inlet.

Use of Muck Pan. In some localities, the hand cleaning method has been superseded by the introduction of a muck pan, or tight sheet-iron receptacle, so located in the inlet as to catch the heavier street sweepings, the surface water coming down with the dirt seeping thru vent holes into the inlet basin. The operation of cleaning the inlet consists of removing the receptacles by means of hooks and dumping the muck direct into the metal body vehicles. This method requires constant supervision in order to prevent overloading of the receptacles and proper maintenance both of the receptacle and the inlet. Its principal advantage is in keeping heavy solid particles from reaching the inlet neck and choking it.

Winter Cleaning. Winter street cleaning in the latitudes of the northern states is probably the most trying problem with which a street cleaning

department has to deal. Dirt continues to accumulate on the streets regardless of the weather and temperature conditions. In the North, the roadways are covered with snow and ice intermittently thruout the winter season, while in the South, snow storms and freezing temperatures are rare. Under the former conditions, the street cleaning problem is largely one of pick-up or spot cleaning by gangmen while the streets are covered with snow and ice, and of machine cleaning whenever the equipment or forces can be used to advantage. Under the latter conditions, however, the street cleaning work progresses quite similarly in both the winter and summer seasons. In certain of the northern states, there is a continuous alternation of freezing and thawing temperatures thruout the winter. In situations of this character, immediate advantage should be taken of every opportunity to do machine or gang cleaning or flushing. To be fully prepared in this matter, it is necessary to keep in close touch with the Weather Bureau and take advantage of anticipated mild weather during which the machine or other cleaning equipment and forces can be operated. It is also of considerable advantage to assign an inspector to each equipment stable to direct the mobilization and dispatch of such of the equipment and forces that it may be possible to use. The instructions issued by these inspectors can be governed more or less by definite prearranged plans considered in conjunction with certain kinds of weather forecasts and observed temperature conditions at certain hours of the day, especially during the morning hours. The governing idea is to have the equipment and forces prepared and if possible on their respective routes ready to begin cleaning operations as soon as the weather and temperature conditions permit this being done. When freezing temperatures prevent the use of water, all machine cleaning must necessarily be suspended in favor of hand cleaning by gangmen. This necessitates increasing the regular cleaning forces at least 40%. In Philadelphia, it has been found that between the middle of Dec. and the middle of March, the machine cleaning equipment can be operated advantageously only on approximately 50% of the working days. All hand cleaning gangs should be under competent and constant supervision, and the gangmen should be equipped with push brooms, hoes, picks, and shovels to facilitate the removal of both loose and frozen dirt and also dirt covered snow and ice. In all winter cleaning, great care should be taken to keep the dust nuisance down to an absolute minimum, as this is often a greater inconvenience and menace to the public than an unclean street. The solution of the winter cleaning problem is principally in taking prompt advantage of every opportunity to work and not in assuming that because of the adverse conditions the streets cannot be well cleaned, little or no effort should be made to clean them. If full advantage is taken of every opportunity a very considerable amount of cleaning can be done and aside from this the municipality will not have to face the problem of removing an excessive accumulation of dirt from its highways with the advent of spring weather.

Relative Ease of Cleaning Different Pavement Surfaces. The effectiveness with which a method of street cleaning can be applied is governed to a considerable extent by the character of the roadway surface cleaned and its physical condition. In making a comparison between the several types of pavement it will be assumed that the roads and pavements considered are new, or in other words, in perfect condition. Assuming further that the ideal road or pavement will have an arbitrary value of 10 with respect to the ease with which it may be cleaned by the method best adapted, the

several types of highway pavements in general use will have the following relative values:

Type of Road or Pavement	Relative Value
Sheet-asphalt	10
Bituminous concrete	9
Wood block	9
Bituminous macadam	8
Vitrified block	8
Cement-concrete	7
Stone block	6
Water-bound macadam with bituminous surface treatment	4
Water-bound macadam	2
Gravel	1
Earth	1

4. Street Cleaning Equipment

Description of Equipment. The minimum quantity and character of equipment necessary for the prosecution of the street cleaning work should be definitely indicated in the specifications and should be of approved construction to fully meet the following requirements:

Squeegees. The horse-drawn squeegee cleaning machines should have a water tank with a capacity of about 500 gal and a cleaning roller set obliquely and geared or chain-belted to the rear axle and having a steel axis and rubber spiral fins.

Automobile Flushers. The automobile flushing machines should be motor-driven high pressure flushing machines of standard design, mounted on a chassis having a capacity of not less than 5 tons, and having a tank for water with a capacity of at least 1200 gal and some form of motor-driven pumps by which the water may be discharged from the nozzles with a pressure of from 35 to 60 lb per sq in, as may be directed, and a capacity to deliver from 100 to 150 gal per min from each nozzle. The machine should be so equipped that the pressure designated can be maintained thruout the entire period of discharge of the water. The nozzles must be elongated, of approved form, and so constructed that their direction may be changed and adjusted as required, and permanently set at any given angle. The machine should be capable of operating at a rate of speed of not less than 3 nor more than 8 miles per hr.

Machine Brooms. The horse-drawn machine brooms should be a 4-wheeled vehicle and have a roller set obliquely and geared or chain-belted to the rear axle. The roller should have a wooden axis and split bamboo bristles, whose length when new shall not be more than 14 in from the axis. Machine brooms should be provided with adequate dust and mud guards.

Sprinklers. The sprinkling machines should be drawn by 2 horses and be of an approved standard type of modern construction substantially built to withstand exceptionally heavy service. The valves should be adjustable to varying swaths.

Collection Vehicles used for the transportation of dirt should have water-tight metal bodies to prevent the contents from leaking when wet. They also should have metal covers to prevent dry contents from being blown out. The bodies of these vehicles should be low, to facilitate their loading and to eliminate the necessity for tossing dirt up any considerable height into the vehicles, which invariably results in more or less of it being scattered by the wind.

Inspection and Adjustment of Equipment. MACHINE BROOMS. In order to get proper results, from both the standpoints of cleanliness and of economy, the machine brooms should be inspected at frequent intervals and so adjusted and operated as to produce their maximum amount of satisfactory work. In the matter of adjustment, special attention given to the following details will do much toward producing satisfactory cleaning results: The broom roller should at all times be so adjusted that its

axis is parallel to the surface of the pavement, otherwise the broom will wear into the shape of a truncated cone, which results in poor work, and necessitates the discarding of the broom much sooner than if it had worn evenly. The broom roller should also be so set that it will press firmly down upon the surface of the pavement, and not merely drag along, otherwise the bristles will not properly engage and dislodge the dirt.

SQUEEGEE MACHINES should be inspected at frequent intervals to see that they are properly adjusted. When not actually engaged in cleaning, the water outlets on the squeegee machine should be shut off and the rubber broom raised a few inches above the pavement surface to prevent the resistance of the rubber fins being impaired or the fins damaged or unnecessarily worn. The following considerations are essential to obtain good results in squeegee cleaning work: The rubber fins should not be torn, distorted or worn thin and should show a proper amount of live resistance. When the average length of the fins projected from the spindle is 3 in or less, or when the width of swath is reduced 1 ft, the fins should be renewed. All water discharge valves should be kept in good condition as leaky valves cause considerable loss of time both in loading water and in working due to the fact that some of the water is constantly wasted and not producing effective results. The axis of the rubber broom should be approximately parallel to the surface of the pavement to prevent the fins wearing unevenly and not properly cleaning the pavement. The fins should press upon the surface of the pavement evenly and firmly and not simply skim over it. The essential function of the fins is not simply to push the water over the pavement but actually to scrub it.

Identification of Equipment. For the purposes of identification, each vehicle should bear on each side a blue enameled steel sign, lettered in white, containing the inscription, Bureau of Highways—D.P.W., followed by the designating number of the district and the serial number of the vehicle. A small blue enameled steel sign, indicating the district number and the serial number of the equipment should be also attached to all bag carriers forming a part of the equipment of the blockman. No duplication of serial numbers should be permitted in any one district. No other signs or lettering should be permitted on either the vehicles or harness. The contractor should be required to keep in stock at all times a sufficient supply of rubber fins, machine brooms, and extra parts to maintain in constant service the minimum force of equipment required by the specifications. The contractor must also see that the cleaning machines are at all times so adjusted that the bristles of the machine brooms and the fins of the squeegees will thoroly accomplish the cleaning results intended. All gangmen engaged in machine, alley, inlet and road cleaning should be provided by the contractor with hand brooms, shovels, picks, hoes, rakes, inlet muck rakes and hooks, and such other equipment as may from time to time be found necessary to properly perform their duties.

Philadelphia Practice Pertaining to Painting of Equipment. It was required that all vehicle equipment be painted at least three times during the year with standard paints, specifications for which are prepared by the Bureau of Highways, and issued to the contractor. If three paintings do not preserve the permanency of the distinguishing colors, painting was required to be done more frequently. The colors of the painting required for the several types of vehicle equipment were as follows: Machine broom, green for body, red for running gear; squeegees, flushers, and sprinklers, yellow for body, red for running gear; bag carriers, maroon; inlet dirt carts and street dirt wagons, brown. The equipment was required at all times to be maintained in a cleanly condition and the contractor was required to install adequate cleaning facilities within his stable or yard as the cleaning of equipment in the street was not permitted. The contractor was also required to present all vehicles and other equipment for inspection at such times and places as might be designated by the district engineers.

5. Street Cleaning Cost Data

Unit Costs of Street Cleaning. Unit cost data covering the several methods of street cleaning used in Philadelphia and Washington are given in the following analyses:

Method of Cleaning	Unit Cost per 1000 Sq Yd of Pavement Cleaned	
	Philadelphia 1916	Washington 1915–1916
Machine broom, horse-drawn equipment	$0.268	$0.186
Squeegee, horse-drawn equipment	0.156	0.139
Machine flushing motor-driven equipment, Philadelphia; horse-drawn equipment, Washington	0.157	0.293
Gang hose flushing	0.474	0.422
Patrol by blockmen	0.152	0.157

The above costs include the removal of street dirt and direct supervision only.

The Philadelphia Unit Costs are based upon the following daily rates of compensation or cost for the several classifications of labor and equipment as indicated.

Classification	Rate per Day
Labor:	
Superintendent	$4.00
Foreman	2.50
Gangman	1.75
Blockman	1.50
Dumpman	1.50
Equipment Units:	
Machine broom, horse-drawn	5.50
Squeegee, horse-drawn	6.00
Flusher, motor-driven	15.00
Sprinkler, horse-drawn	5.00
Dirt cart	3.50
Dirt wagon	5.00

High-Pressure Machine Flushing. Considerable and increasing interest has been evidenced in connection with the high-pressure machine flushing method of street cleaning. The following cost data based upon a working season of 300 days; one 8-hr shift each, is given by Parlin (32) in Table I:

Table I

City	Type of Flushing Equipment	Data per 1000 Sq Yd of Pavement Cleaned	
		Cost	Gallons of Water Used
Chicago	Motor-driven	$0.150	400
Los Angeles	Motor-driven	0.126	450
Rochester	Motor-driven	0.189	440
Worcester	Trolley car	0.186	450
Detroit	Horse-drawn	0.454	700
Milwaukee	Horse-drawn	0.256	400

Cost of Street Cleaning with Motor Equipment. There is no question but that the entire street cleaning equipment in use will eventually be motor equipment. The automobile flusher is very efficient and satisfactory; automobile squeegees and machine brooms are in use in foreign cities and to some extent in this country. In Toronto and Philadelphia during 1916 considerable of the street dirt has been collected and hauled to the dumps by motor equipment and has proved a considerable economy over the horse-drawn equipment. The following is a test of a motor street scrubber:

Table II.—Cost per Day of 10 Hr

First cost of machine		$6100
Depreciation, life of machine, 1200 days	$5.08	
12 gal gasoline at 23 cents	2.76	
2 quarts oil at 15 cents	0.30	
Tires, 25 miles, at 2½ cents	0.63	
Renew machine broom $10, every 6 days	1.67	
Renew squeegee $30, every 100 days	0.30	
Chauffeur	3.00	
Helper	2.00	
18 000 gal water at 4 cents per M	0.72	
	$16.46 per day.	

Records of Tests. Nov. 27, 1916: Time actually worked, 6½ hr; yardage covered, 74 181 sq yd; reduced to 10-hr day, 114 000 sq yd; cost per 1000 sq yd, $0.144. Nov. 28, 1916: Time actually worked, 7⅝ hr; yardage covered, 83 603 sq yd; reduced to 10-hr day, 109 000 sq yd; cost per 1000 sq yd, $0.151. Remarks: Average efficient operating speed, 3½ miles per hr; capacity of tank, 900 gal; effective swath, 7½ ft; gallons per 1000 sq yd, 165; average time to empty tank, 26 min: average time to fill tank, 7 min; average mileage for 10-hr day, 25.

Unit Costs of Cleaning Different Types of Pavements. The cost of cleaning of course varies with the character of pavement. The following costs were compiled from special tests, cleaning the various types of pavements by the machine broom method in Philadelphia in 1914. These costs are exclusive of the cost of water:

Table III.—Machine Broom Work per 1000 Sq Yd

Granite Block			Brick		Wood Block	Sheet-Asphalt	
Traffic			Traffic		Traffic	Traffic	
Heavy	Medium	Light	Medium	Light	Medium	Medium	Light
$0.292	$0.233	$0.210	$0.236	$0.201	$0.232	$0.208	$0.174

The annual cost per square yard of cleaning in the different cities is of very little value unless analyzed; for instance, the above costs of cleaning per yard per year in the different Boroughs of New York City in 1914 compared with the cost of cleaning per yard per year in Philadelphia show that the cost simply varies with the density of traffic and population and the consequent amount of cleaning required. The cost, in the Borough of Manhattan is necessarily very much greater than the cost in the Borough of Brooklyn and the Bronx. It will be observed that the cost of cleaning in Philadelphia has considerably increased in the last five years. This is entirely due to the fact that there never was enough cleaning provided for in Philadelphia. The cost of cleaning in Philadelphia in 1917 is very nearly the same as the cost of cleaning in the Borough of Bronx and Brooklyn, New York City, for 1914, whereas, in order to obtain the same degree of cleanliness, the cost should be somewhat higher in Philadelphia than in the Boroughs of Brooklyn and the Bronx.

Table IV.—Average Annual Costs per Yard of Street Cleaning in New York and Philadelphia

	Cost per Sq Yd of Pavement	Cost per Mile of Highway
New York City, 1914		
Borough of Manhattan	$0.305	$6400
Borough of Brooklyn	0.092	1582
Borough of Bronx	0.096	886
Greater New York	0.168	3136
Philadelphia		
1913	0.058	926
1914	0.065	1062
1915	0.064	1024
1916	0.069	1104
1917	0.101	1629

Average Annual Costs of Street Cleaning. There is no standard for the cost of cleaning per yard per year. The cost is usually governed by the degree of cleanliness required in the different cities and the amount of money available for the performance of the work. In time there will unquestionably be a more or less standard degree of cleanliness required in all of our cities, and until such time arrives the cost per yard per year in each city is of no value with respect to the efficiency with which the work is performed or the degree of cleanliness obtained. It simply indicates the amount of money expended in the respective cities per yard per year for this purpose.

Per Capita Unit Costs of Street Cleaning. Unlike most other classes of work in connection with which it is possible to utilize unit cost data in interpreting results accomplished, street cleaning does not afford the same possibilities. This is due largely to a number of indeterminate factors principal among which is the lack of definition of the relative degree of cleanliness demanded, the condition of the pavement, the use of equipment best adapted to the pavement cleaned, and whether the service is performed under the contract system or by municipal forces. However, in Table V unit costs for street cleaning per capita per annum are given, having been compiled from official reports from the cities indicated:

Table V

City	Year	Estimated Population	Cost per Capita per Annum
Philadelphia	1916	1 725 000	$0.714
Washington	1916	357 749	0.831
Boston	1915	755 905	0.729
Cleveland	1914	650 000	0.455
Detroit	1912	678 000	0.580
Cincinnati	1914	400 311	0.504

Utilization of Street Sweepings. In recent years a number of claims have been made relative to the possibility of utilizing street sweepings as a fertilizing material and of the possibility of deriving revenue therefrom. This subject was quite fully discussed in a report submitted relative to

New York City conditions. The facts noted indicate substantially the status of this matter in 1917. This report states that:

"It is often asserted and as frequently denied that street sweepings have a considerable value as fertilizer for agricultural land. Theoretically, street dirt is of much value as a fertilizer, and possibly of some use as a fuel, but the practical difficulties of utilizing its useful ingredients are too great to make it of substantial benefit. It is in fact a mixed refuse and its composition varies in different seasons in different cities and in different parts of the same city. The elements contained in the sweepings that are of fertilizing value are nitrogen, phosphoric acid and potash. The quantities of these elements found in street sweepings vary within quite wide limits, and are derived almost wholly from the animal excrement. It is difficult to place any fair market value on the nitrogen, phosphoric acid and potash contained in street sweepings, because the market price of these elements not only varies at different times, but the form in which each is found modifies its value for fertilizing purposes. Probably only about one-half of the phosphoric acid is in a soluble form immediately available as plant food. A rough estimate of the values of these elements in 1 ton of street sweepings is at the present, as follows:

8.52 lb nitrogen, at 15 cents	$1278
8.40 lb phosphoric acid, at 5 cents	420
7.32 lb potash, at 5 cents	366
Total	$2064

From this gross value must be deducted the cost of transporting the sweepings to the lands where they are to be used, and their value compared with other fertilizers also must be considered. The great bulk of the gross material that must be handled is the difficulty in attempting to utilize these sweepings on farm lands, since nearly 98% of the mass is inert material. Furthermore, the cost of distributing the street sweepings on farms is disproportionate to their value; and, under usual conditions, sweepings are a far less economical and convenient material for the farmer than the commercial fertilizers to be had in the market. As the better grade of street sweepings have only about half the fertilizing value of stable manure, ton for ton, and as it is becoming more and more difficult to dispose of even the latter material to farmers at a price that will cover the cost of delivery, it will be appreciated how hopeless it is to expect any successful disposition of street sweepings in this way. The use of street sweepings alone for filling lands has been condemned by many sanitary authorities, because the organic matter may undergo fermentation, with exhalation of ammonia or other gases deleterious or obnoxious to those living in the vicinity. Where street sweepings, rich in organic matter, are deposited alone in large masses, there may be ground for serious annoyance and possible injury to health."

6. Administration and Organization of Street Cleaning

Municipal Force vs Contract System. Street cleaning work which from its very nature involves so many more or less irregular operations necessitated by the constantly varying traffic, climatic, atmospheric and local conditions for which it is not always possible to fully and definitely prescribe, requires constant supervision thru personal field inspection of the work performed by each gang or other unit of the organization. This work, as it is also the case with street repairs and other work of a character where it is not possible to fully and definitely specify the detailed manner in which the work shall be performed, should be carried on by municipal forces instead of by the contract system. This necessity is emphasized by the consideration of the dual overhead charges, disproportionate to the cost of the work, which result from the city and the contractor both being required to maintain separate supervisory inspection forces, each of which, however, perform duplicate service, and both of which must ultimately be paid for out of municipal funds. Irrespective, however, of the system under which street cleaning work is performed, there are certain well-defined fundamental, administrative and engineering considerations which

are generally recognized as governing factors in the successful and economical performance of the work.

Purposes Sought Thru Organization. In planning the organization of street cleaning work by contract, the following purposes should be sought:

1. The consideration of street cleaning as an engineering function and the placing of the routine supervision work under the control of district engineers, who are also charged with the responsibility of the construction and maintenance of the pavements in their respective districts, street cleaning being an important part of the maintenance of pavements and should be controlled by the same organization.
2. The classification of streets and roads with respect to the necessary frequency of their cleaning.
3. The institution of specifications that indicate in a definite and concise manner the quantity and character of work to be performed; the minimum force and character of labor and equipment required in the work and the most approved methods of its performance.
4. The institution of a schedule of deductions from the contractor's compensation which would adequately provide for all derelictions relative to labor and equipment required but not furnished, work neglected or improperly performed and other violations of the specifications that tended to lower the standard of the work as a whole.
5. The inauguration of schedules defining definite routes to be followed and the character of equipment to be employed in the performance of the work.
6. The establishment of a system of inspection designed to give the bureau as complete control as is possible with an adequate force of inspectors over the number, condition and character of forces and equipment employed by the contractor, his methods of operation and the results obtained.
7. The adoption of a modern system insuring the prompt and careful investigation of all reports received from the general public of observed instances where the street cleaning work was neglected or not properly performed; and the encouragement of coöperation on the part of the public in reporting all matters of this nature coming to their attention.
8. The installation of unit cost records by which it is possible to determine the actual cost to the contractor of the field work performed, which materially assists in the administrative control of the work, and serves as a basis upon which may be determined the fairness of the prices bid by the contractors, and also makes possible the comparison of costs for similar work in different localities and under varying conditions.
9. The installation of report forms that insure a detailed and accurate record of performances, forces employed, and other pertinent data.
10. The establishment and maintenance of standards of appearance, including the uniforming of all foremen and workmen, and the periodical painting in distinctive colors each type of equipment used on street cleaning work.
11. The encouragement of friendly rivalry among the several contractors, and the promotion of *esprit de corps* among the workmen by the institution of an annual public inspection and parade with the awarding of prizes to the contractors attaining the highest ratings for appearance of men and equipment.

The Administration and Organization of Street Cleaning in Philadelphia as developed by the author while Chief of the Bureau of Highways and Street Cleaning, 1912 to 1917, will illustrate the details of methods required to properly control this work.

Routine Supervision. The regular supervision of the street cleaning work was under the jurisdiction of the several district engineers who also had charge of the collection of ashes, rubbish and garbage and the construction and maintenance of pavements in their respective districts. In addition to maintenance a close supervision over the field inspection work performed by the several street cleaning inspectors assigned to each district, and making adjustments to the work schedules of the order or manner in which the street cleaning work should be performed, the district engineer also kept in touch with the complaints received from the general public concerning the performance of the work.

Investigation of Complaints. In all branches of the public service coöperation on the part of the citizens in reporting apparently unsatisfactory conditions coming to

their attention is generally recognized as a most valuable asset toward the attainment of ideal conditions. On this account it should be the policy not only to invite constructive criticism but also to furnish every facility for so doing. Upon the receipt of a report at the main office of the improper or non-performance of street cleaning work there should be originated a complaint form upon which is indicated the location and nature of the reported conditions, the date, the name and address of the complainant, the serial number of the complaint and the district number. A record of the existence of the complaint should be made in a complaint register by recording the complaint serial number, the name or address of the complainant, the district number and the date of the complaints transmitted to the district office for investigation. Upon receipt at the district highway office, the complaint should be promptly issued to an inspector for investigation and report. In instances where a complaint is originally received by the district office it should be investigated as usual and in the meanwhile the main office should be advised by telephone of its existence and a serial number assigned to it. After being approved by the district engineer the complaint forms should be forwarded to the main office. Upon receipt of the complaint form at the main office the open entry in the complaint register should be closed out by entering the date of the complaint's return. To insure that no complaint investigation is neglected for an unreasonable length of time or overlooked the complaint register should be checked each week and all complaints for which final reports have not been received investigated.

Record Forms. To assist in the administration of the street cleaning work the following record forms were provided: (1) Work routine schedules; (2) inspectors' daily reports; (3) district engineers' daily reports; (4) special test unit cost data reports; (5) special test unit cost data summary forms; (6) monthly unit cost data reports; (7) complaint forms; (8) complaint register sheets.

Work Route Schedules. To insure that the street cleaning work may proceed in orderly sequence and with a minimum of lost motion and the least inconvenience to the public, work or route schedules should be compiled outlining the work of each gang for each working day of the week. These schedules indicate the identifying serial number of the district, route, and gang to which they apply, the character of cleaning to be performed, the quantity and character of labor and equipment to be employed, and the names, limits and character of pavement of the highways to be cleaned The number and limits of the highways included in any specific route schedule and the sequence of the cleaning was based upon the consideration of arranging the highways to be cleaned as nearly contiguous as possible and providing for a fair day's work. The planning of up-to-date and economically arranged route schedules was considered to be a very important feature in connection with the efficient performance of street cleaning work and on this account the district engineers were required not only to personally direct their preparation but also to assign an assistant engineer or inspector to constantly keep in touch with the manner in which the schedules were carried out to determine their practicability and to make any revisions necessary.

Inspectors' Daily Reports. Each inspector assigned to the supervision of street cleaning work was required to submit a daily report to the district office. In this report was indicated the following data: the district number; the date; the weather conditions; the quantity and character of labor and equipment in each gang employed on each of the several classifications of cleaning and at the dumps; the condition of the uniforms and equipment; the quantity of dirt collected; record of any derelictions; and the hours during which the inspector was on duty.

District Engineers' Daily Reports. From the several inspectors' daily reports, the district engineers compiled in duplicate a daily report, Fig. 1, for each street cleaning district, indicating in composite form all of the data shown in the daily reports of the several inspectors assigned to that district. The original copy of this report was forwarded to the main office and the duplicate copy was retained in the district office.

Unit Cost Records. To assist in the administrative control of the street cleaning work and to furnish data by which may be determined the degree of efficiency of the performance of the work, there should be compiled for each district a monthly report, Fig. 2, indicating the unit costs for each character of street cleaning work performed. This report should be compiled from the force employed and dirt collected data contained in the monthly summary and the record of the yardages cleaned as indicated in the route schedules. In detail, this report indicates for each character of street cleaning the total cost, the area and unit costs both in terms of 1000 sq yd of pavement

cleaned and 1000 cu yd of dirt collected. When more refined data is desired for either engineering or administrative purposes special test cost data should be collected and compiled in the main office. This special test cost data taken collectively should cover such highways, types of pavement and classes of cleaning at such seasons as are considered to be typical of the conditions prevailing throughout the city during the entire year. For each street cleaned during these special investigations the cost data report should contain the district number, date, the classification of the cleaning, the name and limits of the highways cleaned, the length, width and area in square feet of the surface cleaned, the weather conditions, the character and condition of the

pavement cleaned, the volume of the traffic, classified as either light, medium or heavy, the character, quantity and time of each class of labor and equipment employed, the quantity in gallons of water used, the quantity in cubic feet of dirt removed, and the inspector's name. These reports should be submitted to the main office where the information they contain can be transferred to a cost data summary, one summary being maintained for each classification of cleaning, which should contain in composite form the total area of the highways cleaned, the costs per 1000 sq yd of pavement cleaned in time and money of each class of labor and equipment employed, and the total quantity of gallons of water used and dirt collected per 1000 sq yd of pavement cleaned.

Labor. It should be required that all employees engaged on street cleaning work be thoroly able-bodied and capable, both physically and mentally of performing their duties in a satisfactory manner, and able to speak English satisfactorily.

Uniforms of Employees. It is universally conceded that the general effect of uniforming any working force is to not only increase the efficiency of the work thru promoting *esprit de corps* among the workers, but also to visualize to observing persons that a certain sense of order prevails in the organization. These considerations are always desirable, but especially so in connection with the municipal public service. All of the supervisory and working forces should be uniformed. Each superintendent or foreman was required to wear a dark gray uniform, consisting of a coat, trousers and cap. All other employees were provided at all times with at least two suits of white

uniforms, consisting of coat and trousers. During the months of June, July, Aug. and Sept. the blockmen and gangmen were allowed to omit coats, provided a white shirt of an approved type was worn and suspenders omitted in favor of belts. During the same months foremen and drivers were also allowed to omit coats provided an approved type of shirt of the same color as the uniform, and belt were worn. Drivers wore an approved type of brown canvas hat in the summer and a brown cap during winter. All other employees were provided with a white helmet for summer wear and a white cap for winter wear. All uniforms were required to be maintained in a clean condition and all employees wearing wash uniforms were required to appear in a clean uniform on each Monday morning. As a means of identification each employee should wear at all times a badge on his hat or cap having indicated thereon, Bureau of Highways—D.P.W., and also the identifying number of the street cleaning district. Each employee should also be provided with a three-quarter length rubber coat, rubber hip boots and rubber hat to protect them while working during inclement weather.

Working Hours. The working hours should be from 7 A.M. to 12 M. and from 1 P.M. to 6 P.M., except during the months of Nov., Dec., Jan. and Feb., when due to darkness the work should be discontinued at 5 P.M. It is desirable in the business district to perform all street cleaning work at night except during the winter months.

Annual Inspection and Parade. In order to encourage friendly rivalry between the several superintendents and to promote *esprit de corps* among the employees, and especially to afford the general public an opportunity to judge whether a proper standard is being maintained, there should be an annual public inspection of the labor and equipment of each of the several districts. This annual inspection should be in the form of a parade, and when a clean-up week campaign is to be held it is very desirable to have the parade just prior to clean-up week as a means of advertising the event. On this occasion each district should be required to have both the uniforms and condition of the equipment present the most creditable appearance possible.

COLLECTION AND DISPOSAL OF ASHES, RUBBISH AND GARBAGE

7. Collection and Disposal of Waste

Sanitary and Economic Considerations. The main factors which govern the methods of collection of ashes, rubbish and garbage are sanitary and economic considerations. The sanitary considerations require that these waste materials be collected with sufficient frequency and disposed of in a manner not prejudicial to the public health. The economic considerations relate exclusively to the methods of collection and disposal, the principal methods being the separation method and the mixed method. The separation method consists in the separation of ashes, rubbish and garbage by the householder, their storage in separate receptacles and collection by the municipal collectors in separate vehicles, while the mixed method consists in the storage of these waste materials in the same receptacle and their subsequent collection in the same vehicle. Both of these methods are sanitary. But, from an economic standpoint, in most of the cities in the United States the separation method is the least expensive. In many instances, in European cities, this is not so; the reason probably being, as statistics show, that there is about four times as much rubbish and garbage placed out for collection in this country as there is in Europe. Consequently, there would be more revenue derived from the disposal or reclamation of these materials when collected separately, than there would be in Europe. Furthermore, most of the cities in the United States are growing rapidly and afford considerable opportunity for the advantageous use of ashes as a filling material either in grading the streets or in reclaiming lowlands, etc. Therefore, it may be stated, that in most cities in the United States the separation of waste materials and the disposal of garbage by the reduction method, the reclaiming of rubbish thru modern rubbish

disposal plants and the utilization of ashes for filling material is the most economical method of handling this problem. In many of the European cities, where there is very little use for ashes as a filling material and it is not possible to derive much revenue from the reclamation of rubbish and garbage on account of the relatively small quantities placed out for collection, the mixed incineration method of waste disposal is probably the most economical. There is no question, however, that the mixed incineration method is the most convenient to both the householder and the municipality, as it is very difficult to educate the people to separate waste materials, and, as a matter of fact, the only way to insure the separation of waste materials is thru the rigid and continuous enforcement of the laws by the police.

Classifications of Domestic and Trade Wastes. The several general classifications of domestic and trade wastes and the character of the materials included in each may be enumerated and defined as follows:

Ashes, which includes ashes in an amount of 400 lb per week per building from coal or other fuel, and floor sweepings such as may accumulate in connection with the ordinary conduct of dwellings.

Rubbish, which includes all discarded materials from residences and, in a reasonable amount, from places of business, such as bottles, paper, rags, bedding, furniture, clothes, shoes, leather, carpets, broken glass, crockery, cane, metals, rubber, Christmas trees and decorations, shrubs, vines, grass and leaves, in a reasonable quantity from each building each week and also the contents of highway rubbish receptacles.

Garbage, which includes all refuse of animal and vegetable matter, which has been used, or was intended to be used, as food for human consumption, and all dead animals, or parts thereof, not intended to be used as food, in a reasonable quantity from each home or other non-commercial building and not exceeding 1 bushel from each store or stand each collection day.

Trade Waste, which includes earth, sand, brick, stone, lumber, plaster, wall paper and any other material or sweepings that result from building operations, fruits or other vegetable matter from wholesale dealers; and garbage exceeding 1 bushel in quantity, or oyster or clam shells from restaurants, hotels or other places of business.

Per Capita and Total Annual Production of Waste. In considering the per capita per annum production of waste this term will be assumed to include only the household or domestic waste materials, such as ashes, rubbish and garbage. Due to the absence of a uniform system of keeping municipal records and the different methods of service operations employed it is not possible to obtain extensive or altogether reliable data from many municipalities. Several of the larger cities are maintaining records which will give this data, and it is expected that such a practice will become universal. Table VI has been complied from official reports:

Table VI

City	Year	Estimated Population	Pounds per Capita per Annum		
			Ashes	Rubbish	Garbage
New York City, Boroughs of Manhattan, Brooklyn and Bronx........	1916	4 655 668	....	...	210
Philadelphia............	1916	1 725 000	773	86	260
Washington............	1916	357 749	416	97	292
Boston.................	1915	755 905	936	...	203
Cincinnati.............	1914	400 311	689*	...	....

*This is a composite value for ashes and rubbish combined.

In order to give a comprehensive idea of the fluctuation in the quantities of waste materials collected during the several months of the year, the curves in Fig. 3 are shown which represent the quantities of ashes, rubbish, garbage and street dirt collected and

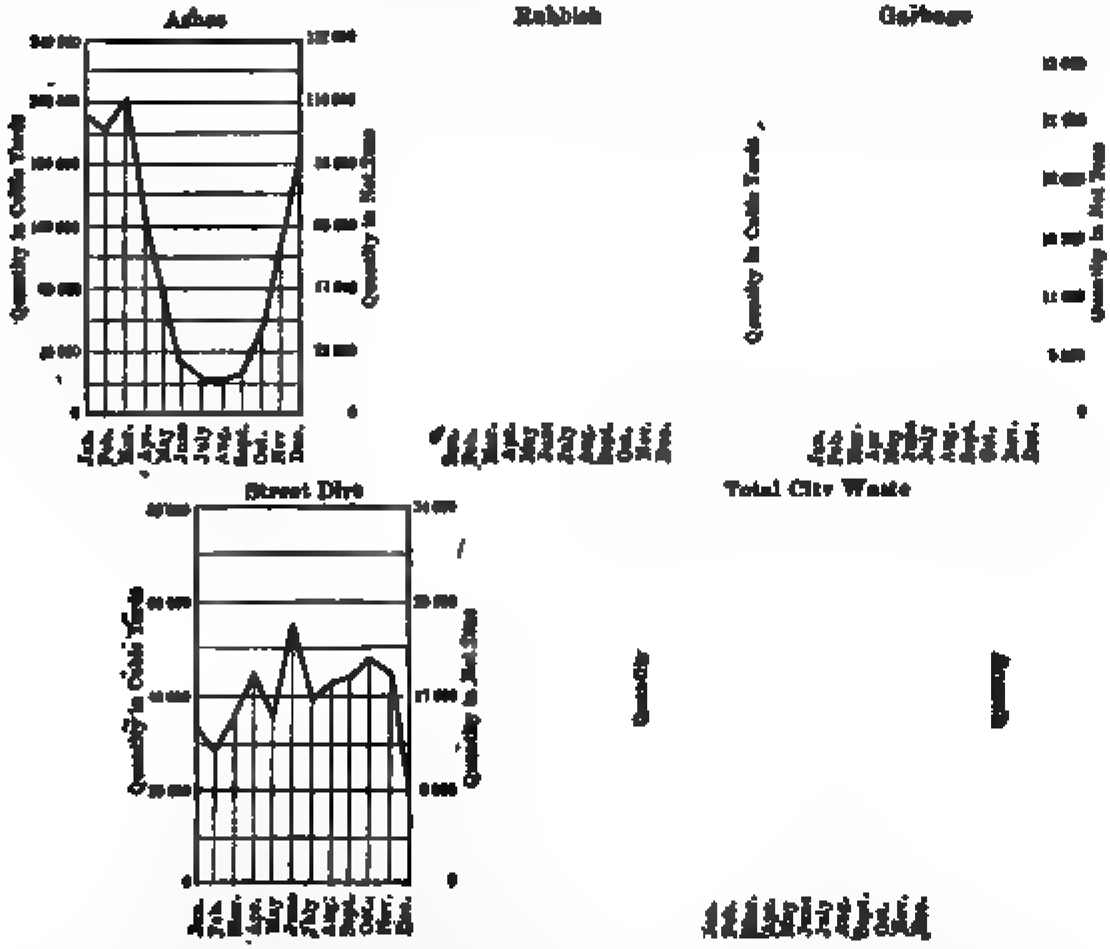

Fig. 3. Waste Collected During 1916 in Philadelphia

disposed of in Philadelphia during the year 1916. These curves may be considered as illustrative of the average conditions existing in the larger cities. It should be particularly noted that rubbish and garbage increase in quantity during the summer months while ashes increase very materially during the winter months.

Per Capita Unit Costs of Waste Collection and Disposal. The unit costs per capita for the collection and disposal of ashes, rubbish and garbage, will vary considerably

Table VII

City	Year	Estmated Population	Unit Costs per Capita per Annum			
			Ashes	Ashes and Rubbish	Rubbish	Garbage
Chicago	1912	2 287 520	...	$0.361*	..	$0.164

Detroit	1912	673 000		.....	.....	.162

*These are composite values for ashes and rubbish combined.

according to the method of disposal employed and whether the service is performed under the contract system or by municipal forces. The lack of a uniform and adequate system of records makes it difficult to obtain reliable data for the purpose of intercity comparison. Table VII has been compiled from official reports.

Weight per Cubic Yard of Waste Materials. Since 1910 a number of investigations have been made to determine the average weight per cubic yard of the different classes of domestic waste. Probably the most extensive investigation of this character was conducted in the District of Columbia in 1915 by Irvin S. Osborn. Based upon 41 studies of the weight and volume of rubbish, the average weight of rubbish was found to be 201.4 lb per cu yd, while the maximum weight observed was 386.8 lb per cu yd and the minimum weight 130.0 lb per cu yd. A number of studies have also been made in Philadelphia with the result that the following weights in pounds per cubic yard were determined upon: Ashes, 1100; rubbish, 220; garbage, 1100; street dirt, 850.

Collection of Trade Waste. In connection with the municipal collection of waste materials, the classification generally known as trade waste is intended to include all waste materials that result from distinctly industrial or commercial activities. While, in the interest of public health and safety from fire hazard, it is considered to be properly a municipal function to collect and dispose of all waste materials resulting from the ordinary conduct of homes and minor places of business, yet it has never been considered equitable to the tax payers at large to include as a public duty such waste materials as are produced thru the operation of business enterprises.

In Philadelphia, it is not the policy to collect or dispose of so-called trade waste at municipal expense. The few instances that may possibly be regarded as exceptions to this principle are in the case of garbage from retail stores, which is collected in a quantity not to exceed one bushel, and the concession which requires the contractor to receive and dispose of, when delivered to his disposal plant, decayed vegetables or fruits from wholesale dealers without cost to party delivering it.

Incineration Method of Mixed Waste Disposal. In general the incineration method of mixed waste disposal may be described as follows: The mixed waste, which may include ashes, rubbish and garbage, is hauled to the disposal plant and dumped from the vehicles into hoppers from which it is transported by belt conveyors to the upper floor of the disposal plant where it is discharged into large tanks or silos. The bottoms of the silos consist of a large mesh inclined grate, which moves rapidly back and forth. This device enables the material to be fed uniformly and without compression thru the conduits into the incinerating furnaces. The incinerating furnaces consist of air-tight insulated steel cylinders reinforced with thick fire brick walls and arched tops. The grate on which the material to be incinerated rests is turned continuously and carries with it in rotation practically the entire charge of rubbish. Some grates are conical and this type of grate has the advantage of giving larger grate surface for the distribution of the charge and also serves to properly direct the air currents, which insures better combustion. The revolving grate insures constant agitation of the charge thus insuring the displacement and ejection by means of gravitation of the ashes and clinkers as quickly as the combustible content of the waste has been consumed. Directly beneath the incinerating furnaces are large hoppers, which receive the ashes and clinkers ejected from the furnaces. These hoppers are equipped with controlled outlets, which permit of their contents being discharged into vehicles or cars by which it may be removed from the plant. Generally speaking, the handling of the waste from the time it enters the plant until it leaves in the form of ashes and clinkers is automatic and requires very little labor except that necessitated by periodic inspections to insure that the equipment is operating properly. However, the furnaces require constant attention. The

heat generated in the incinerating furnaces is conveyed thru flues to boilers usually of the water tube type where steam is generated, which in turn furnishes steam and electric energy, for heat, light and power purposes at the plant or elsewhere. In practically all situations where either part or all of the waste is disposed of by the incineration method, there is the same opportunity to produce more or less steam or electric power for sale. Considerable experimenting also has been carried on for the purpose of utilizing the furnace product, which is known as clinker. To a limited extent clinker has been used in making bricks and as an aggregate in cement-concrete work, but no appreciable amount of revenue has been obtained from the utilization of this material.

8. Collection and Disposal of Ashes

Collection of Ashes; practice recommended for Philadelphia by the author. Ashes should be collected from each home once each week and on a day separate from that on which rubbish is collected. The householder should be required to deposit the ashes in tight receptacles, preferably metal, upon the sidewalk near the curb. The total weight of any one receptacle and contents should not exceed 150 lb and the total quantity of ashes that will be removed from any building should not exceed 400 lb per week. When more than one building, as in the case of a row of apartment dwellings, is heated from a central heating plant, the amount of ashes that will be removed should not exceed an amount equal to 400 lb for each building so heated. If, however, the heating plant is in a building constructed and used exclusively as a heating plant, only 400 lb of ashes should be removed by the contractor. It should be required that the contents of receptacles be emptied in the collection vehicles without spilling, and the receptacles returned to the sidewalk near the curb line, carefully and without injury. Each ash collection route should be under the direct supervision of a foreman, employed by the contractor and whose duties should be confined exclusively to that route. The contractor should be required to furnish a sufficient number of laborers and vehicles to sweep up and remove from the streets all ashes blowing or spilling from the receptacles, and this force should be required to operate at a distance of not more than one block behind the collecting forces. Ashes should be conveyed to the dumps by vehicles, barges or trolley cars, the latter two being loaded by gravity from the collecting vehicles in especially constructed loading stations.

Use of Ashes as Filling Material. Clean ashes may be utilized in the grading of highways and filling in of municipally owned lowlands and also private property upon which conditions, such as mosquito-breeding pools, have been formally declared to constitute a nuisance.

Dumps for Ashes. See Art. 9.

Calorific Analysis of Ashes. As there is apparently little prospect of domestic ashes being utilized in the immediate future except as a filling material, it is rather unnecessary to investigate into its mechanical or chemical composition. Due, however, to the fact that ashes constitute a considerable portion of the domestic waste material which is disposed of in a number of cities by the mixed incineration method it is desirable that the calorific or combustible value of ashes be known. In order to determine some such data 45 samples of domestic ashes were recently analyzed by the Bur. of Mines, U. S. Dept. Int., with the average results given in Table VIII. In interpreting this data it should be noted that cinder and dust are arbitrary classifications designating respectively the larger particles and the finely-divided material which collectively constitute ashes and have been separated by sifting.

Table VIII

Material	Percentage of Weight	Moisture	Dry Material			British Thermal Units as Obtained From	
			Volatile Matter	Fixed Carbon	Ash	Sample Tested	Equivalent Weight of Dry Coal
Cinder......	51.4	2.05	3.53	51.10	45.30	7858	7932
Dust.......	48.6	4.55	5.09	15.99	78.87	2875	3074

9. Collection and Disposal of Rubbish

Collection of Rubbish; practice recommended for Philadelphia by the author. Rubbish should be collected from each home or other building once a week and on a day separate from that upon which ashes are collected. In the interest of clean streets, householders should be encouraged to store rubbish while waiting collection within their premises and should be required to display in some conspicuous place on the removal day, a notice card containing the inscription, Call for Rubbish, furnished by the contractor, indicating that rubbish is upon the premises awaiting removal. All rubbish should, however, be stored at a point on the premises readily accessible to the collector. Whether stored within the premises or on the footway, the secure bundling of rubbish or the use of bags or other suitable tight receptacles should be required in order to prevent the rubbish being scattered on the highways. The contractor should be required to furnish a sufficient number of laborers and vehicles to sweep up and remove from the streets all rubbish blowing or spilling from the receptacles and this force is required to operate at a distance of not more than one block behind the collecting forces. Rubbish should be conveyed to the dumps by either vehicles, barges or trolley cars, the latter two being loaded by gravity from the collecting vehicles, in especially constructed loading stations. After the collection vehicles are loaded with rubbish, it should be required that they be taken at once to the dump and if not reclaimed within 24 hr thereafter, disposed of, either by burning or by covering with clean earth or ashes, so as to eliminate the possibility of its becoming a nuisance by being blown over the adjacent properties.

Dumps for Ashes and Rubbish. All rubbish dumps should be provided with standard fire hydrant connection and sufficient hose to reach all portions of the dump. Both ash and rubbish dumps should be operated at all times in the manner as required by the Bureau of Health. All dumps should be frequently inspected to insure that they are being operated in a sanitary manner and with due regard to minimizing fire hazards.

Rubbish Disposal Plant. Aside from lessening the cost of the collection service thru the profits accruing from the systematic reclamation of such of the materials as have a commercial value, the establishment of rubbish disposal plants would relieve the nuisances which exist in the form of rubbish dumps thruout the outlying sections of a city, where it is frequently very difficult to maintain sanitary conditions and also to entirely eliminate the fire hazard, both of which conditions are an injustice and constitute a

menace to the health and property of the citizens living in the vicinity of these dumps. In general it may be stated that approximately 50% of all household rubbish consists of reclaimable material or, in other words, material that can be recovered and sold to produce revenue. The reclamation method of rubbish disposal such as is employed in most of the modern plants may be briefly outlined as follows: The rubbish is hauled in the collection vehicles onto an elevated platform at the disposal plant and dumped into bins alongside of which are located belt conveyors. The rubbish is raked onto the conveyor as fast as required. The conveyor then passes thru a long horizontal channel on either side of which are stationed a sufficient number of pickers to pick out what is termed the reclaimable or saleable materials. Each picker is assigned to pick out a certain kind of material; for instance, one picker's duty will be to pick out the glass bottles, another the rags, another the metals and another papers, etc. The worthless material is allowed to remain on the conveyor, which carries it to the incinerating furnaces where it is destroyed.

Mechanical Analysis of Rubbish. Comparatively few investigations have been made of the mechanical composition of domestic rubbish. This is due to the fact that such data is seldom sought except in connection with consideration of a disposal plant problem and relatively few municipal rubbish disposal plants are operated in the United States. One of the most extensive investigations of this character was conducted under the supervision of Irvin S. Osborn in the District of Columbia, during a period of 8 months, Nov., 1914, to Aug., 1915, inclusive, and the results of the mechanical analysis of 16 346 cu yd of domestic rubbish, having a weight of 32 926 lb, collected during that period was as given in Table IX.

Calorific Analysis of Rubbish. In connection with the consideration of the mixed incineration method of domestic waste disposal, it is essential that the calorific or combustible value be known of the predominating materials, which collectively constitute approximately one-third of the volume of all household or domestic waste. In order to make available some data of this character, the Bur. of Mines, U. S. Dept. Int., made a number of calorific analyses of rubbish as collected and it was found that 1 lb of rubbish, including dirt, metals, glass and other noncombustible materials yielded 5500 British thermal units as compared with 11 000 British thermal units yielded by 1 lb of dry coal. Analyses were also made of two samples each of the predominating combustible materials with the results given in Table X.

Selling Prices of Materials Reclaimed from Rubbish. During the period, 1914 to 1917, the prices obtained for sorted scrap and waste materials have risen steadily due largely to conditions brought about by the European War. In some instances these prices have advanced so high as to warrant their being considered abnormal and not suitable for purposes of comparison when normal conditions shall have been restored. For this reason the data here indicated has been taken from the annual report of the Division of Street Cleaning, Department of Public Service, City of Cleveland, for the year 1914, for which year the prices may be considered as practically normal. The

prices indicated in Table XI are for sorted materials recovered from domestic rubbish in the municipal rubbish disposal plant.

10. Collection and Disposal of Garbage

Collection of Garbage. It should be required that all receptacles used for the storage of garbage while awaiting collection be durable, watertight and covered and preferably made of metal, and that the receptacles be stored in a safe place in the yard where they are not likely to be overturned by passing traffic and will be readily accessible to the collector. The collectors should be required to remove the entire contents of each receptacle, replace the cover and transfer the garbage to the removal vehicle in a water-tight receptacle. It should be required that garbage removal vehicles be at

Table XI

Rubber:	
Hose	0.0025 lb
Mixed	0.0400 lb

least half covered while being loaded and fully covered while in transit. All garbage from buildings where a contagious disease exists should be collected separately from other garbage and in vehicles specially provided for the purpose. The garbage collection contractor should also be required to remove dead animals from the highways and alleys immediately upon their presence being reported to him. In Philadelphia, garbage is collected every day in the thickly populated sections of the city, four times a week in the less thickly populated sections, and three times a week in the suburbs.

Reduction Method of Garbage Disposal at the Philadelphia Plant. The process of the reduction of garbage at disposal plant is as follows: The raw garbage is delivered at the central disposal plant by both vehicles collecting from the near-by territory and by scows which load at wharves on both the Delaware and Schuylkill Rivers to which vehicles haul from the more distant portions of the City. Mechanical chain pan conveyors transfer the garbage from the scows and from the bins into which the vehicles from an elevated platform unload their contents into elevated movable hoppers which can be discharged into any one of the several digesters. When a digester, which has a charging capacity of 10 tons has been filled and sealed, steam under a pressure of 75 lb is injected and the garbage is allowed to cook for a period of from 8 to 12 hr, depending upon the general character of the garbage being treated. At the termination of the digestion period, the cooked garbage is placed into hydraulic presses and by means of compression the solid and liquid matter is separated, the latter of which is conveyed to a central collector thru floor channels. The liquid matter, which, as it comes from the presses consists of a mixture of water, grease and more or less solids in suspension in the form of muck and silt, is passed thru a series of separating tanks, which separates by gravity the grease, which is then pumped into storage tanks to await shipment in tank cars or barrels. After the water is separated from the residual solid matter by means of evaporation the solid matter is stored for mixture later with the tankage. The solid product of the presses, which is known as tankage, is dried in revolving heated cylinders and then placed in revolving percolators which have a capacity of about 10 tons each. After the percolator is filled and sealed, gasoline is pumped thru the material. The gasoline dissolves any grease remaining in the tankage and is then drawn off into distilling tanks in which the grease is retained and the gasoline is driven off as vapor by means of steam heat and is conveyed to a condenser and finally to storage tanks. In order to prevent the loss of tankage grease this percolating or washing operation is repeated three or four times, if necessary. The tankage material is then discharged from the percolator, dried and screened and any foreign matter, such as glass, crockery or metals, removed. The screened tankage is mixed with the solid matter recovered from the liquid product of the presses and is again dried, after which it is ground, screened and stored or loaded for shipment. It will be noted that, except for the water content and a relatively small proportion of rubbish all of the by-products derived from the reduction of garbage are marketable and it may be stated at prices which yield a considerable profit over the plant operation costs. The grease consists principally of fatty acids and glycerol and these substances are utilized respectively in the manufacture of toilet and laundry soaps, soap powders and cleansers and glycerine, nitro-glycerine and dynamite. The tankage is utilized principally as fertilizer either as a whole or as a base from which are derived such materials as ammonia, ammonium sulphate, phosphoric acid, lime phosphate and potash.

Garbage Reduction Plant Operation Unit Costs. For the year 1914 the unit costs per ton of garbage reduced in the Columbus, Ohio, plant were as follows:

Item	Unit Cost	
Administration:		
Supervision	$0.197	$0.221
Clerical services	0.014	
Analytical services	0.010	
Labor:		
Firemen and enginemen	0.123	0.936
Operators	0.221	
Laborers	0.491	
Repairmen	0.101	
Operating supplies:		
Coal	0.314	0.535
Electricity	0.067	
Gasoline	0.109	
Miscellaneous	0.045	
Maintenance:		
Materials	0.091	0.128
Renewals	0.037	
Miscellaneous	0.039	0.039
Total		$1.859

The following operating materials were consumed per ton of garbage reduced:

Material	Unit of Quantity	Quantity Consumed
Coal	Ton	0.225
Electricity	Kilowatt-hour	4.480
Gasoline	Gallon	0.884

The net operating results per ton of garbage reduced were as follows:

Revenue thru sale of by-products	$3.085
Cost of operation	1.859
Net profit	$1.226

Unit Prices Received for Garbage Reduction By-Products. The average unit prices received during 1914 for the sale of the by-products of the Columbus Ohio, garbage reduction plant were as follows: Grease, $4.325 per 100 lb; tankage, $7.410 per ton. The selling price received for tankage was governed by the percentage of contained fertilizing elements as follows: Ammonia, $1.71 per ton; potash, $0.70 per ton; tri-calcium phosphate, $0.10 per ton.

Mechanical Analysis of Garbage. The mechanical composition of domestic garbage varies considerably during the several seasons of the year and to a more or less extent in different localities. The percentage of solids of tankage increases during the summer months while the percentage of grease increases during the winter months. Considering these variations, the following analysis will indicate the average composition of garbage during the entire year: Water, 75%; solids, organic, 15%; solids, inorganic, 6%; grease, 4%. The term organic solids includes all materials otherwise known as tankage, while the term inorganic solids is intended to include materials other than true garbage, such as cans, crockery, glass, etc, which must be removed from the tankage during process and are of practically no reclaimable value. While dead animals could possibly be included in the classification of garbage, yet in many cities only the smaller animals are so classified. The larger dead animals, such as horses and cattle, are usually sold by their owners to private rendering establishments. The average yield of dead animals when reduced is as follows: Water, 78%; grease, 5%; bones, 5%; other solids, 12%. The hides, especially those of the larger animals, are usually disposed of separately.

Chemical Analysis of Garbage. For a period of 1 year, during 1914 and 1915, the Bur. of Soils, U. S. Dept. Agric., conducted a rather extensive investigation to determine the chemical composition of garbage. Samples were taken in different localities and during every month of the year. In general, the results of the analyses of the individual samples seemed to indicate that the character of the population making the garbage did not influence the chemical composition of such garbage. The average results of all analyses conducted thruout the year on both raw and dry garbage were as given in Table XII.

Table XII

Material	Percentage of Weight	
	Raw Garbage	Dry Garbage
Moisture	73.85	None
Combustible	22.52	86.22
Grease	5.12	20.05
Ash	3.63	13.91
Nitrogen	0.71	2.87
Phosphoric acid, P_2O_5	0.39	1.52
Potash, K_2O	0.28	1.07

Chemical Analyses of Garbage Reduction By-Products. The average analysis of the by-products of the Columbus, Ohio, plant for the year 1914 were as follows:

TANKAGE: Tri-calcium phosphate, 8.08%; ammonia, 3.58%; moisture, 3.10%; grease, 1.20%; potash, 0.78%; other, 83.26%.

GREASE: Unsaponifiable, 2.910%; moisture, 1.520%; impurities, 0.131%; pure grease, 95.439%.

Classification of Dead Animals Removed from Highways. An interesting record covering a period of 5 years, 1911 to 1915 inc., of the kinds of dead animals removed from the highways in the District of Columbia, gives the following analysis which may be assumed to represent the average of conditions existing in the larger cities:

Table XIII

Kind of Animal	Number Removed	Percentage
Cats	58 463	63.7
Dogs	26 338	28.7
Horses	3 029	3.3
Rats	1 939	2.1
Chickens	961	1.0
Cows	14	0.1
Miscellaneous	1 012	1.1
Total	91 756	100.0

11. Equipment for Collection of Ashes, Rubbish and Garbage

Horse-Drawn Vehicles vs Motor Trucks. Horse-drawn vehicles are used in most cities for the collection of ashes, garbage and rubbish. Since 1915, however, some cities have tried out collection with automobile trucks and trucks hauled by tractors. There is no question but that on very

short hauls averaging 1 mile or under, the collection by horse-drawn vehicles is the most economical.

From experiments carried on in Philadelphia during 1916 it would appear that even with a haul of 2 miles the house to house collection of ashes by automobile trucks was not economical with a carrying capacity of under 10 cu yd. With a capacity of 10 cu yd or more the truck proved to be an economy over the horse-drawn vehicle. In studies made in Washington on the cost of collection of ashes during 1915 it was found that with an average haul of 1 mile that 50% of the time of the vehicle was consumed in loading, hence, unless the distance of the haul is considerably over 1 mile, it would not be an economy to collect with the motor vehicles.

The most economical method of collection would probably be a house to house collection by horse-drawn vehicles, the material to be hauled to a loading platform within the radius of ¼ to ½ mile of the collection district, and then dumped into automobile trucks to be hauled to the dump. However, a great deal of the street dirt is caused by the horses used in the street cleaning, collection of ashes, garbage, rubbish, etc, and this fact, together with the better appearance of the automobile trucks over the horse-drawn vehicles and the more desirable and flexible means of operating will eventually entirely eliminate the horse-drawn vehicle as a means of collecting the city waste.

Description of Equipment. Specifications should provide that all equipment either permanently or temporarily operated by the contractor should be of approved construction and fully conform to such requirements as the following:

Ash Vehicles. The ash vehicles must be strong and tightly constructed and be equipped with a one-piece durable canvas cover, supported on a frame, both of which are described in detail elsewhere in this Article. Metal ash vehicles shall be designed so that the top of the box will be not more than 4 ft 9 in above the ground and shall have a capacity of not less than 3.75 cu yd of material without piling, and so that the angle of the bottom of the wagon when dumping shall be not less than 30° with the ground.

Motor-Driven Ash Vehicles. Motor-driven ash vehicles shall be so designed that the top of the box will be not more than 5½ ft above the ground, and shall have a capacity of not less than 4 cu yd.

Rubbish Vehicles. The rubbish vehicles must be tightly constructed so as to prevent their contents spilling or blowing therefrom and must be equipped with a one-piece canvas cover.

Garbage Vehicles. The garbage vehicles shall have strongly constructed, water-tight, metal bodies, and be equipped with tightly closing metal covers.

Identification. Each vehicle shall bear on each side a blue enameled steel sign, lettered in white, containing the inscription, Bureau of Highways—D.P.W., followed by the designating number of the district and the serial number of the vehicle.

Ash Vehicle Covers. The inauguration of the use of dust-proof covers on ash collection vehicles has supplied a long-felt necessity, as the dust nuisance which exists during the loading of uncovered ash vehicles constitutes a serious inconvenience to the travelling public and also in the absence of covers more or less ashes are spilled or blown onto the highways. With a proper frame and cover, it is possible to partly cover the vehicle while being loaded and entirely cover it while in transit. Specifications for frames and covers might embody the following description of details of construction:

The ash vehicle cover frames are made of malleable iron pipe, 1 in in diameter and 1½ in angle iron. They consist of a ridge pole set at a height of 30 in above the upper edge of the flash boards and are supported on two loops, made of either angle or flat iron, the front loop set in a vertical position and the rear loop inclined outward. Both loops are attached to the body of the vehicle, the rear loop being reinforced with a diagonal brace. Both the iron pipe ridge pole and the diagonal braces at the rear of the wagon are fastened to the front and rear loops with rivets or bolts. The front and rear loops and the diagonal braces are bent to conform to the contour of the interior

sides of the vehicle and are attached thereto by means of bolts spaced 6 in apart. The entire frame is painted with three coats of gray paint. The canvas used in making the cover is that material known as No. 1 white duck, and of a weight determined on a basis of 18 ounces weight to 22 in in width of material per lin yd. The front curtain consists of one piece of canvas cut to the contour of the front loop and with enough extra material to pass completely around the loop frame so that it can be securely sewed together and kept permanently in place, or instead of this, metal-bound eyelets are provided along the entire edge of the curtain for tying it to the loop. The bottom of the front curtain entirely covers the face of the 2 by 6 in nailing board and is attached thereto with screw bolts inserted thru metal-bound eyelets in the curtain placed 12 in apart. The body cover is made of material 22 in in width, the sections being sewed together from a point 6 in outside of the front loop to the rear loop and carried over to form the tail curtain which consists of a separate section sewed to the main cover around the contour of the rear loop. All joints in the covers are provided with an additional reinforcing strip of canvas 1½ in in width, sewed with not less than 6 stitches to the in. At the junction of the ridge pole and the rear loop the section forming the tail curtain is slit down the center on an angle so as to provide an overlap of at least 8 in at the bottom, the corners being provided with metal-bound eyelets for tying the closed cover to the opposite sides of the vehicle. The cover is finished with a 4-in pocket stitched along the edge with 4 additional pockets stitched along the body of the canvas parallel to the edge and located at equi-distant points on either side of the ridge pole. Hickory battens, 6 in number, measuring 2⅛ by ½ in and of a length projecting 6 in beyond the front loop and extending to the outer edge of the rear loop, are inserted in these pockets. The ends of all battens are reinforced with a section of 8-ounce russet leather measuring 5½ by 4 in each, fastened with 6 rivets, 2 receiving the batten by being clinched thru the center. The cover is also provided with at least three 1-in leather straps, 1 in in width rivetted to the canvas for attaching the cover to the ridge pole. All other fastenings of the cover to the frame or body of vehicle are made thru metal-bound eyelets with the best quality ⅜-in sisal rope.

Painting of Equipment in Philadelphia. It is required that all vehicle equipment be painted at least three times during the year with standard paints, specifications for which are prepared by the Bureau of Highways and issued to the contractor. If three paintings do not preserve the permanency of the distinguishing colors, painting is required to be done more frequently. The colors of the painting required for the several types of vehicle equipment are as follows: Ash vehicles, gray; rubbish vehicles, red; garbage vehicles, brown. The equipment must be at all times maintained in a cleanly condition and the contractor is required to install adequate cleaning facilities within his stable or yard. The contractor is also required to present all vehicles and other equipment for inspection at such times and places as may be designated by the district engineer.

12. Administration and Organization of Waste Collection and Disposal

Municipal Force vs Contract Systems. In the interest of efficient service and economy and also to insure sanitary operating methods, it is specially desirable that the collection and disposal of ashes, rubbish and garbage be performed by municipal forces rather than under the contract system, and that the city own and operate disposal plants. The contractor for this character of service will naturally try to collect these waste materials at as small a cost as is possible, and consequently will not take pride in keeping the equipment up to the proper standard, nor will he employ as high a grade of labor as it is desirable to employ in this kind of work where the collectors are continually coming in contact with the householders. With respect to the disposal of garbage it should be borne in mind that, generally speaking, there is a profit of practically $1 a ton over operating expenses on every ton of garbage received at the disposal plant, exclusive of the cost of collection. It has also been demonstrated that a rubbish disposal plant can be operated in such a manner that it will pay the plant

operating costs, interest and depreciation charges and still produce a small revenue thru the sale of steam and electric power. But when this disposal work is performed by contract, the very nature of the work, which necessitates an enormous initial capital outlay for the plant and equipment, eliminates in itself all possibility of competition, whether the contract be for a 1, 5 or 10-year period. In the first place it would not pay to construct a plant for a 1-year contract. It should also be borne in mind, that if a contractor decides to bid on a 5 or 10-year contract, and will be obliged to meet competition at the end of that time, he will naturally make the contract price sufficiently high to include all operating, interest and depreciation charges, and yield a profit during the period for which he has the contract, and also to pay the interest charges on the invested capital during the time that the plant is likely to be idle due to his losing the next contract. It will be seen, therefore, that where there are two or more plants in existence in a community, the municipality must indirectly pay the interest and sinking fund, and possibly other charges on each of the plants instead of on only one as would be the case were the plant owned by the municipality.

Principles Governing the Organization of the Work. In working out a system of collection and disposal of ashes, rubbish and garbage the following purposes should be sought:

1. The consideration of the collection and disposal of household wastes, including ashes, rubbish and garbage, as an engineering function comparable in importance and possibilities of development with any other municipal engineering function.

2. The determination of the most economical and sanitary method of collection and disposal, including rubbish and garbage disposal plants for separation collection method and incinerating plants when the mixed collection method is determined upon.

3. The inauguration of all possible improvements in the collection and disposal methods with special respect to promoting economical, sanitary and safe operating methods and to preventing waste matter from littering the highways or creating unsanitary conditions or fire hazards at the disposal dumps or plants.

4. The consideration of the reclamation and sale of rubbish and the reduction of garbage and sale of the by-products as an asset by which the costs of its collection and disposal in a sanitary manner in disposal plants could be reduced to a minimum.

5. The installation of adequate report and record forms which provide complete and definite records of performances, which may be used to assist in the administrative control of the work.

6. The institution of a system for determining the unit and total costs of operating the service by which it may be possible to make comparisons of these costs with those for similar work in other municipalities.

General Organization Employed in Philadelphia, 1912 to 1917, under direction of the author while Chief of the Bureau of Highways and Street Cleaning. For the purposes of the collection of ashes, rubbish and garbage, which was accomplished under the contract system, the City was divided into eight districts whose boundaries are coterminous with the highway districts, except that in two instances a single highway district contains two service districts and in another instance two highway districts are considered as one service district. In each district the work was under the direct supervision of the district engineer who also had charge of street cleaning and the construction and maintenance of pavements. The numeri-

cal designation of the service districts were identical with those of the highway districts except in the instances where two service districts were included in the territory occupied by one highway district.

Collection Schedules. To insure that the collection may proceed in orderly sequence and at times that will be known to the public, each contractor was required to have personally served on the responsible occupant of every home and other building in his respective district at the beginning of each year an instruction and collection route schedule card, Fig. 4, indicating the days upon which collections will be made

☞ HANG THIS UP FOR REFERENCE

Notice to Housekeepers

GARBAGE

Will be collected between the hours of 7 A.M. and 6 P.M.

☞ Garbage must be kept separate from ashes and household waste.

Extract from Specifications

Kitchen garbage shall be called for and removed from all buildings, without charge to the occupants, on Mondays, Wednesdays and Fridays from January 1st to June 14th inclusive, and October 16th to December 31st, inclusive; and on Mondays, Wednesdays, Fridays and Saturdays from June 15th to October 15th, inclusive.

Garbage must be deposited in covered, water-tight vessels that can be easily and quickly handled by one man, and placed at points readily accessible to the garbage collector, who must remove the entire contents of said vessel.

Garbage from retail grocers and fish dealers shall be collected daily (except Sunday) in quantity not to exceed one (1) bushel from each store or stand.

Decayed vegetables or fruits from wholesale dealers is not considered as garbage to be collected by the Contractor, but the same shall be received and treated as other garbage, without cost to the *party delivering*, when delivered at the disposal works of the Contractor.

It is intended that waste paper and other refuse shall not be mixed with the garbage; but should any such matter be found with the garbage, it must be removed by the Contractor.

The Contractor shall remove all dead animals promptly, as they are found and reported. . . . All animals shall be removed in a manner satisfactory to the Director (of Public Works), and at all times covered during transportation.

Galvanized Garbage Cans (with cover), all of the same grade, are recommended as follows:

No. 02, capacity 6¼ gallons, price, about 85 cents.
No. 00, capacity 5¼ gallons, price, about 70 cents.
No. 000, capacity 4¼ gallons, price, about 55 cents.
No. 0000, capacity 3 gallons, price, about 35 cents.

The above-referred-to containers can be purchased from most all dealers in this kind of ware at approximately the prices named. The use of uniform and durable receptacles of the kinds described will have great influence on the sightly condition of our streets, effectiveness of collections, and also upon the health of the citizens.

All complaints should be addressed to

BUREAU OF HIGHWAYS

January 1, 1915 **Room 232 City Hall**

Fig. 4

and giving instructions to the occupant relative to the character of materials that may be classed as ashes, rubbish and garbage, and quantity of each class of material that will be collected and character of receptacles in which they should be placed. This card also contained extracts from the governing ordinances and requests that reports relative to the improper or non-performance of these services should be made to the Bureau of Highways. In certain districts, which were populated largely by

foreign speaking peoples, these cards are printed in four languages, namely, English, German, Italian and Hebrew. No changes were made in the scheduled collection routes unless approved by the Chief Engineer and provided that the affected householders should have received 24 hours' notice of the intended change. These schedules served as a guide to both the contractor's forces and the municipal inspection forces.

Frequency of Collections. The frequency of the garbage collections was based upon the actual requirements in the different sections of the City as governed by the density of population and the season of the year, while the frequency of the ash and rubbish collections was determined upon as a matter of fixed policy. The several classifications of collections were as follows:

GARBAGE: Class A, six collections per week, daily, except Sun.; Class B, four collections per week on either Mon., Wed., Fri. and Sat.; or, on Mon., Tues., Thurs. and Sat.; Class C, three collections per week, on either Mon., Wed. and Fri. or, Tues., Thurs. and Sat.

ASHES AND RUBBISH: Class D, one collection per week on a definite day according to a pre-arranged schedule.

Hours of Collection. All collections of ashes, rubbish and garbage were required to be made between the hours of 7 A.M. and 6 P.M. except that no ashes or rubbish were collected after 12 M. on Sat. In the interest of convenience to the public a further exception was made with respect to the collection of ashes and rubbish in the central business section, where the collections were made between the hours of 6 P.M. and 6 A.M. from April to Nov., inclusive, and during the months of Jan. Feb., March and Dec., between the hours of 3 P.M. and 10 P.M. On the following holidays no collections are made: New Year's Day, Fourth of July, Labor Day and Christmas.

Routine Inspection. The routine inspection of the collection and disposal of ashes, rubbish and garbage was performed by specially trained inspectors reporting to the respective district engineers. In general, each inspector was responsible for the work performed in a certain definite section of the district territory to which he was regularly assigned. He was required to verify and report the character and numerical strength of the force and equipment at work and to note the condition of the uniforms and equipment for which definite standards are provided.

Investigation of Complaints. See Art. 6.

Report and Record Forms. To assist in the efficient administration of the work the following report and record forms were provided: (1) Collection instruction and schedule cards, two cards, one each for garbage and for ash and rubbish collection respectively; (2) Inspector's daily reports, covering compositely the collection of both ashes and rubbish and garbage; (3) district engineers' daily reports, covering compositely the collection of both ashes, rubbish and garbage; (4) monthly unit cost data reports, two forms, one each for garbage and ash and rubbish collection; (5) complaint forms, two forms of distinctive colors respectively, one each for garbage and ash and rubbish collection complaints; (6) complaint register sheets.

Inspectors' Daily Reports. Similar to Inspectors' Daily Report described in Art. 6.

District Engineers' Daily Reports. Similar to District Engineers' Daily Reports described in Art. 6. See Fig. 4.

Contractors' Daily Reports. Each contractor was required to submit a daily report to the main office, in which he was required to report on the same kind of data as is required by the district engineer's daily report.

Comparison of Daily Reports. Each day the data shown on the respective daily reports for each district, of the district engineers and the contractors, were recorded by the main office on the comparison summary, one report form containing daily entries covering a period of one month. Any discrepancy discovered in the daily comparison of the data contained in the two reports was immediately investigated. At the close of the month, the records of the forces employed by the contractor were summarized and multiplied by the estimated unit costs to the contractor for each character of labor and equipment, which gave the probable total cost of the field operations to the contractor, which data was also used in connection with the compilation of the unit cost data report.

Unit Cost Records. Similar to Unit Cost Records described in Art. 6.

Labor and Uniforms of Employees. See Art. 6.

SNOW REMOVAL

13. General Considerations Relative to Snow Removal

Historical Development. There is probably no problem confronting a municipality which is at times of more vital interest to the public, and at other times so entirely forgotten than the problem of snow removal in the larger cities. During snow storms everybody is intensely interested even to the extent of advocating supposedly new or more expeditious methods of snow removal, but during the spring, summer and fall the general public entirely forget this important municipal function. Snow removal is distinctly an emergency problem and the more experience one has with this problem the more convinced one will be of the fact, that the human element is the dominating factor. There may be introduced scientific methods of snow removal that would operate successfully on a pleasant day, but which would be a complete failure in a storm when the conditions are such that none but the sturdiest type of laborer could work. Furthermore, the labor market is a factor that must always be considered. Some winters it is very easy to secure the services of all the laborers desired, while during other winters it is very difficult to get men for this work even with increased wages, so that any system that may be devised to cope with this problem will at some time or another fail unless the human element has been given due consideration. Until about 1912, the administrative arrangements and the working methods employed in connection with this work were very crude, this being probably due to the fact that snow removal was not considered seriously as an engineering problem. Prior to 1912 it was the custom in most cities to wait until a snow storm was over before beginning the work of removal. In other words, the city did not begin to dig itself out until after the storm had ceased. As a consequence, the highway traffic was often very seriously inconvenienced. Since 1912, however, very considerable study has been devoted to improving the organization and the general methods of snow removal, so that at present it may be stated that every detail of either organization, equipment or methods of operation that past experience has shown the need of have been amply prepared for and called into service. The highly satisfactory results produced thru the operation of the snow-fighting forces since 1912 has proven conclusively that the efficient administration of snow removal work is fundamentally a matter of preparedness based upon an exhaustive study of the requirements of the work and the establishment of a proper organization, the institution of a definite and adequate procedure, and the thoro instruction and drilling of the snow-fighting forces in the requirements of their respective duties.

The 1914 Snow Removal Conference. Snow removal in municipalities was the subject of more intelligent study during 1914 than probably ever before, which was evidenced by the Snow Removal Conference held that year in Philadelphia, at which were present representatives from 16 of the largest eastern cities. At this conference it was realized that the problem of snow removal must obviously be considered differently in different cities as its solution is dependent upon such variable elements as climate, population, width of streets, density and character of traffic, location of sewer systems, available disposal places and other local conditions, to say nothing of the financial policy of the municipality. It was deemed impossible to formulate anything but the most general suggestions, and yet it is found that even so vital a matter as the financial policy does not affect the main problem, except in the extent of the work.

Fundamental Principles of Snow Removal. In connection with the prosecution of snow removal work the general policy should be first, the

disposal of snow in the shortest possible time and at the lowest practicable cost; second, to eliminate the possibility of interruption of vehicular highway traffic during the snowfall by plowing the snow into windrows adjacent to the curbs; and third, to remove and dispose of the snow and ice from pedestrian highway crossings, vicinity of fire hydrants, gutters and sewer inlets and entire areas of congested business highways. One of the greatest difficulties in snow removal work is that there are seldom two storms presenting the same problem. For example, it is obvious that the difficulties of removal to be encountered in a blizzard carrying a considerable depth of snow are far greater than those encountered in a storm when the temperature is very mild and the snow is easily handled. There are innumerable considerations that present themselves in almost every storm that are somewhat different from every other storm. Sometimes it is possible to do far more satisfactory work panning and flushing than it is possible to do in the average storm. For instance, in one storm, preceding the snow a sheet of ice may be formed on the pavement. It would, therefore, be folly to remove all of the snow from this ice, as the snow is then the only means of footing for horses. The eccentricities of snow storms are limitless, but it would seem, all things considered, that the most reliable method for opening up the streets for traffic at the present time is to rely principally on the use of motor driven plows.

The Committee on Resolutions of the 1914 Snow Removal Conference Made the Following Recommendations embodying the underlying principles of snow removal work:

1. The plan of organization and the system to be employed should be worked out in advance of the snow season. This preliminary work should involve: (a) A plan of coöperation of all branches of the municipal government; (b) the formulation of a skeleton organization composed of all of the available city forces, such as engineers, inspectors, timekeepers, laborers and teams; (c) the division of the city into zones and the determination of a definite method of work for each zone. The various members of the organization should be assigned to these zones and the responsible officials familiarized with the duties expected of them. The character of work to be performed in the different zones may consist of merely the regulation of opening crosswalks and gutters and otherwise generally assisting pedestrian traffic and the run-off of snow, or it may consist in the complete removal of the snow from the streets. Owing to the general increase in motor traffic and the concentration of business in definite office districts and to the general public demand for increased urban facilities, the present tendency is to increase the scope of the work involving the complete removal of the snow from all main thorofares and business streets.

2. The work of removal should commence as soon as the snow has covered the pavements and the indications point to the storm continuing, and the operations should be carried on continuously. This as a principle, is successfully followed by street railways in the removal of snow from their track space, and by some cities.

3. The carrying capacity of the sewer system should be utilized as far as possible to get the snow away from the streets. The use of the sewers which reduces both the haul and handling to a minimum involves two operations: Namely, getting the material to the catch basins or manholes, and then putting the material into the sewers. The first operation can best be done by loading into wagons or trucks and hauling to suitable manholes, or by the use of scrapers or graders. The problem of getting the material into the manholes in the least time and with the least interference with the traffic opens up a field for consideration of the question of special forms and special locations of manholes, designed to be used solely for this purpose. The method of flushing the snow with fire hose into catch basins may have a limited application, but it is too unreliable to have any general value, as it depends on weather conditions.

4. When practicable, where there is only a small area to be cleaned, the work should be performed directly by the municipality by day labor. This method of operation is the most flexible and the most easily administered and it obviates the necessity of measurements and checking under the contract system. The work can also be performed by day labor in large areas by adopting the following method: The depart-

ment to advertise and go out into the open market and hire teams to haul the snow for so much per yard, the price to be determined upon by the department and to represent a fair estimate of the cost of the work and a fair profit. This, of course, would throw the work open to anyone owning one team, or a hundred or a thousand or more teams, depending upon the amount of work to be performed, and would not leave the department dependent upon any one or more contractors. In this method, as well as when the work must be performed by contract system, a method of measurement as simple and accurate as possible should be used. The practicability of having work done by the municipality will depend, among other things, on the immediate availability of an appropriation. It is essential for the proper conduct of the work, whether by day labor or contract, that appropriation for snow removal should be made in advance of necessity for the work.

5. Coöperation should be sought with the traction companies and use made of adjustable plows and sweepers to open roadways adjacent to street railway tracks at the time that the work of clearing the tracks is being carried on.

6. Efforts should be made to obtain the coöperation of the public and to instruct the householders in the method of removal of snow from private premises in such a way as to least impede the city's work. Where the sidewalks are of greater width than would be necessary to handle the reduced volume of pedestrian traffic, which can be expected after a heavy snow, the snow instead of being entirely cleared from the sidewalk and piled in the roadway should be left on the sidewalk near the curb line to be later removed by the city when opportunity presents itself.

7. The police force of the city should coöperate with the street cleaning forces and the services of patrolmen as inspectors should be utilized as far as possible. The police in particular should give attention to the enforcement of regulations governing the removal of snow from the sidewalks or from a portion thereof.

Snow Removal from Country Roads. Until the advent of the automobile, country roads were very little traveled in the winter, but it is not an exaggeration to state that at this time certain country roads are more important than a number of city streets and should be kept open for travel all the year round, not only as a means of passenger transportation, which is important enough in itself, but as a number of our inter-city highways are very extensively used by motor trucks for the transportation of merchandise and all classes of food.

As the motor truck transportation continues to increase, it is perfectly obvious that more attention must be given in the future to the removal of snow from these main highways, and this can be very readily taken care of by the use of snow plows attached to motor trucks. Their work, however, as in the removal of snow from city streets, would have to start as soon as the snow begins to make any appreciable headway, rather than waiting until the storm is over. Should this not be done, in many cases the snow will be so deep that it would be impossible to remove it with plows and traffic would be temporarily suspended.

The time is not far distant when it will not only be desirable but necessary to build snow fences on a number of our important inter-city highways at locations where the snow is likely to drift to any great extent.

Snow removal from the main country roads which are used for the transportation of merchandise, etc, will be in the future just as important a consideration in the upkeep of highways as the repair of pavements themselves, and will therefore become a very important function of state highway departments.

14. Practical Methods for the Removal and Disposal of Snow

The Three Principal Methods of Snow Disposal and their limitations may be briefly described as follows:

1. Plowing the snow to the side or center of the street by means of

automobile or horse-drawn plows, after which it is piled and then loaded into vehicles and hauled to dumps, which may be sewer manholes or rivers, and in some cases open lots.

2. PANNING, which consists of pushing the snow into sewer manholes by means of a specially constructed form of scraper, usually constructed of iron, which may be likened to a very large snow shovel.

3. FLUSHING the snow into sewer inlets or manholes. This is done by means of a hose or by running power flushing machines up and down the streets and forcing the snow to the gutter, following with a gang of men brooming the melted snow into the sewer inlets.

The first method of disposal, on which the main dependence is placed, plowing the snow and then piling and hauling it to dumps, is what might be termed the general method of disposal. This work starts when the snow begins to fall and plows should be kept continuously at work during and after the storm until all of the snow is removed from the streets.

The method of disposal by panning the snow into sewer manholes should only be considered as supplemental to the main method of carrying on this work by means of plows. It is not practical or possible to dispose of all of the snow by the panning method; in the first place it is impossible to get enough men to remove the snow by this method in a short enough time to avoid seriously interfering with the traffic; secondly, it is practically impossible to get an appreciable number of men to work on this method of disposal during a storm on a cold night, which is a condition to be met with in the greater number of snow storms.

The method of disposal by flushing cannot be carried on except when the temperature is above freezing and is therefore only supplemental to the main method of plowing, piling and hauling to the dumps.

Too much stress cannot be laid upon the fact that in order to successfully cope with the snow removal problem and open the streets to traffic at the earliest possible moment, the main dependence must be placed on the plows, supplementing this of course with the employment of as many men as it is possible to obtain to work on the panning method or pushing the snow into sewer manholes, and if the weather is warm enough, the employment of as many gangs and flushing machines as possibly can be used to dispose of the snow by flushing. In the plowing method of disposal it is of course desirable to have the dumps as close as possible and this means the universal use of sewers, dumping it into the manholes. Arrangements must be made where there is insufficient flow of water to connect the manholes with the water system. On Sundays and holidays in business sections of the city where factories are closed down, it will almost always be necessary to supplement the flow of water in the sewer thru a connection with the water system in order to have sufficient flow to carry off the snow.

Use of Sewer System. When the method used is that of plowing, shoveling into trucks or carts and hauling to dumps, the length of haul becomes of paramount importance, and it is obvious that the use of sewer manholes as dumps, with the sewer system to carry the material to the rivers, is the most economical method which can be used, as it reduces both the haul and the handling to a minimum. In PHILADELPHIA the sewer system has been used since 1912, but in some cities the authorities in charge of the sewer system have objected to the use of sewers as snow carriers.

This condition existed in NEW YORK CITY until exhaustive experiments were made by John T. Fetherston, Commissioner of Street Cleaning, New York City, and W. Goldsmith, Inspector of Public Works, Borough of Manhattan, in 1914. The following conclusions were a result of these experiments: (1) Under ordinary conditions

snow will melt in a sewer 300 ft from the point where it is dumped; (2) the theoretical number of B.T.U. necessary to melt snow checks the actual test in the sewer; (3) 2 cu yd per min was found to be the maximum rate at which it was possible to shovel snow into 24-in diameter sewer manholes; (4) there is much more heat in sewage than is necessary to melt within 300 ft all the snow that can be dumped into sewers; (5) syphon sewers carry snow away as well as others.

It is also found by experiment that: (1) Snow can be dumped by wagon-loads into sewers carrying 10 cu ft per sec or more; (2) panning can be employed where sewers have 3 cu ft per sec or more flowing in them, and where the velocity is greater than 1 ft per sec; (3) the snow can be shoveled into sewers having 2 cu ft per sec flowing in them, if the velocity is greater than 1 ft per sec.

In some cases the experiments show that where the velocity was great and the flow small, much snow can be carried away. For instance, at one location a sewer had a flow of 5.3 cu ft per sec, the velocity, however, being 10 ft per sec, yet with this slight flow the sewer made an excellent dump.

In referring to the use of sewers for snow disposal, at the conference on snow removal held March 8, 1916, A. E. Kalbach, Deputy Street Cleaning Commissioner, Borough of the Bronx, New York City, stated: "Until the winter of 1914–15 extensive use had not been made of sewers for the removal of snow. Water transportation has always been cheapest, and by using the artificial waterways of the city, melted snow reaches the same destination as that which is hauled to and dumped into the river, and with the most expensive steps of the latter operation eliminated.

"In February, 1914, the proposition for the complete utilization of sewers was advanced. The general plan proposed was that snow should be removed from the streets by men equipped with regulation pan scrapers who would shovel snow into the sewer manholes while the snow is falling and as fast at it falls, and that such plan would be successful provided: (1) That flow in sewers be of sufficient depth; (2) that the remuneration to the emergency force be sufficient to obtain the men in character and number required to perform the work.

"The advantages of such a system were pointed out to be: (1) Economy in disposal of snow; (2) economy to all persons engaged in transportation, by elimination of traffic congestion due to snow-blocked streets; (3) cleaner streets, because department vehicles could adhere more closely to their normal schedules, and thus prevent the dumping of household refuse on the snow piles in many sections of the city when the regularity of the service is upset, owing to street conditions and traffic congestion.

"Upon the adoption of the general plan a survey of sewers was made to determine the depth and velocity of sewage in 1098 miles of sewers. The information was plotted on maps. Snowfall data for the previous 46 years were collected and analyzed. Weather conditions were studied and department employees instructed to record observations of the barometer, wet and dry thermometers, force and direction of wind, cloud forms and directions from which they were moving, to be used in making weather predictions.

"The result of the first season's work was satisfactory. Tables used in this paper are taken from the report of Commissioner Fetherston to Mayor Mitchel, comparing work on previous plans of contract work on yardage and area bases as compared with the combination of snow fighting and snow removal. The rate of removal was double the best record obtained in the season of 1913–1914, which itself was double the best previous record on the truck system of removal. The cost per cu yd, 12.1 cents, compared with the average cost of 57.3 cents in the six preceding winters, and with the lowest record in that period of 33.7 cents.

"The speed of snow removal by snow fighting in 1914–1915 more than doubled the best previous record, and more than trebled the average record for the period of 1902–07, when the area basis of measurement was employed. The cost per cubic yard of snow removed by use of sewers in 1914–1915 was equal to one-fifth the average cost of removal on the area basis, and one-fourth the cost of the lowest record made from 1902 to 1907."

It will be noted in the following table that the cost in 1914–1915 in New York was 12 cents per cu yd. This was largely due to the removal of 3 858 912 cu yd of snow at 7 cents per cu yd by panning or shoveling the snow into sewer manholes, and a large percentage of this work was done on Easter Sunday in April, 1915, when the weather was very mild.

Table XIV.—Comparison of Annual Snow Work Data

Winter	Number of Working Storms	Depth Working Storm Inches	Days Work	Cubic Yards Removed	Total Cost	Cost per Cubic Yard	Average Cubic Yards Removed per Day
1907–08......	4	23.0	45	1 125 447	$413 556	$0.367	25 009
1909–10......	3	30.0	44	1 873 236	1 405 628	0.750	42 573
1910–11......	5	23.7	46	3 625 716	1 470 904	0.560	57 081
1911–12......	5	17.7	39	1 590 235	870 389	0.547	40 775
1912–13......	1	11.8	8	496 047	245 623	0.495	62 006
1913–14......	3	38.2	43	5 180 825	2 473 343	0.477	180 484
Averages......	3.5	24.1	37.5	2 148 584	1 146 574	0.533	57 296
1914–15......	3	22.4	16	4 318 481	533 892	0.121	269 905

In Philadelphia the snow and ice removed from the highways are disposed of by being dumped either into the sewer thru manholes, many of which have been especially constructed for the purpose, or directly into either the Delaware or Schuylkill Rivers, either at the wharves or thru manhole openings in bridge floors. Where the normal flow in a sewer is insufficient to quickly carry away the dumped snow and ice, a water jet has been installed which serves to increase the flow and this flushing is regulated by the inspector stationed at the dumping station. Considerable difficulty has been experienced with sewer manholes which are located between the rails on heavy traffic trolley lines, and arrangements are being made where sewers are of sufficient depth to construct sewer manholes on the shoulder with chutes to the sewer.

Snow Plow Outfits. Aside from the horse-drawn plows, which are ordinary road scrapers, commercial motor trucks can be equipped with plows. These are of two types, one has the plow attached to the front of the truck and the other simply hauls a road scraper. Experience has demonstrated that those plows attached to the front of a motor are more efficient in every way, particularly with a wet, heavy snow than the plows hauled by trucks, for the reason that the road scraper is comparatively light and tends to swing away from the snow, whereas this difficulty is not experienced when the plow is on the front of a heavy motor truck, particularly when the truck body is loaded. The driver's seat on the motor plow should be closed in order to keep him at work at all times, even under the most trying conditions. The specification requirements for this type of plow are as follows:

Automobile Plow Outfits. All automobile plow outfits must consist of a motor truck of not less than 4 tons' capacity and in front of which must be securely fastened an adjustable plow blade set at an angle of about 45°, and not less than 10 ft in length and 1 ft in depth; or, a motor truck of the same capacity, hauling a scraper with a similarly constructed plow blade. Each such plow outfit must include a driver and one extra man.

Horse-Drawn Plow Outfits. When the use of horse-drawn plow outfits is permitted they must consist of a plow or road scraper of a type to be approved by the Chief Engineer, drawn by 4 horses and manned by 2 drivers and 1 operator.

Hauling Vehicles. All vehicles used for snow removal should be required to have an ultimate carrying capacity of at least 2 cu yd. The box structure should be so enclosed on at least three sides as to give the vehicle a total full load capacity of at least 2 cu yd, and to prevent the spilling of the contents. The inspector should be required to measure and compute the cubical contents of each type of hauling vehicle for which he issues loading tickets and to indicate this capacity on the ticket by punching or marking out in indelible pencil the proper yardage indication.

Method of Determining Quantity of Work Performed. The number of cubic yards of snow and ice removed and disposed of by a contractor should be determined in the following manner: For each vehicle loaded to its rated capacity the loading inspector should issue to the driver of the vehicle a loading ticket indicating by cubical measurements the contents of the vehicle. After the vehicle's full-sized load has been delivered to the assigned authorized dump and properly dumped and disposed of the dumping inspector should issue to the driver a dumping ticket in exchange for the loading ticket which the driver surrenders to the dumping inspector.

Snow Removal from Sidewalks. One of the weak features in snow removal work is that the snow is very often removed at night from the roadways and the following morning all of the snow from the sidewalks is shoveled into the street that has already been cleaned. In order to cope with this situation in Philadelphia, thru the coöperation of the Police Department a regulation was introduced which required that the occupants of homes and other buildings thruout the city should, 6 hr after the snow had ceased to fall, remove it from the footways abutting their property, leaving a passageway at least 4 ft in width and piling the snow on the footway between the curb and a line 3 ft within the curb. This does away with the practice of shoveling snow from the sidewalk into the street after it has been cleaned of snow.

Use of Cinders on Slippery Roadways. On or before Nov. 1st of each year cinder boxes should be placed on the highways at the locations where traffic is heavy and it is known that slippery conditions will develop. These boxes, which should be kept filled with cinders at all times, should have a capacity of not less than 14 cu ft. They should contain the lettering, Cinders for Slippery Pavements. The cinders should be spread upon the highways just as soon as dangerously slippery conditions develop, whether or not the snow and ice have been entirely removed from the roadway surface. When necessary, extra loads of cinders should be hauled to the locations where needed, distributed directly upon the highway from the hauling vehicles by a mechanical spreading device.

15. Experimental Methods for the Removal and Disposal of Snow

Classification of Methods. Of the experimental methods none have thus far been found to be practical for snow removal work in municipalities. These devices and methods include asphalt surface heaters, elevator grading machines, compressing boxes, special sewers under the curbs and various melting devices, such as steam pipes under the sidewalk and roadway. A number of investigations and experiments have been conducted to determine the practicability of removing and disposing of snow by mechanical melting methods. The more recent investigations were outlined by Fetherston (21d). Extracts covering the important experiments described are included as indicated by references. Up to 1917 no mechanical melting process has been found to be economically practical.

Melting Snow by Steam Methods (21d). Preliminary to the investigation of the melting by steam method of snow removal and disposal it was necessary to determine the latent heat and density of snow as it falls. A series of experiments were accordingly conducted during 1915 by Otto H. Klein, Director of the Standard Testing Laboratory, New York City, with the following results:

Latent Heat of Snow as it Falls. Four determinations were made, giving values of 80.8, 81.7, 79.6 and 81.7 calories, with an average of 80.9 calories, equivalent to 145.6

B.T.U. This represents a very fair agreement with the theoretical values of 80 calories, or 144 B.T.U. The factors influencing this result include: (1) Initial temperature of the snow; (2) percentage of water in the snow; (3) final temperature of the mixture. With the exception of the second factor, the first and third may be readily controlled by, first, the use of an accurate thermometer graduated to hundredths of a degree, and second, having two men perform the experiment, with one of them constantly at the calcrimeter taking readings; in this way an accurate estimate of the difference in temperature may be made. Furthermore, if the snow can be obtained at low temperatures it is safe to assume that it is dry and contains no free water.

Density of Snow as it Falls. Four determinations were made on the snow as it fell, and the following figures for the density were obtained:

Number of Determination	Density	Corresponding to Lb per Cu Ft
1	0.13	8.1
2	0.14	8.8
3	0.17	11.3
4	0.11	6.9

The temperature of the air at the time of the experiments averaged 0.6° C (35.8° F). The density of snow is dependent upon three conditions: (1) The compactness of the snow crystals; (2) the water content; (3) the content of foreign bodies. With regard to the presence of foreign bodies, the density of snow will vary with the locality and may become as high as 1.31. It is therefore obvious that the density of snow is a variable quantity. According to J. C. Trautwine, the weight of 1 cu ft of freshly fallen snow will vary from 5 to 12 lb, depending upon the humidity of the atmosphere; and 1 cu ft of snow when moistened and compacted by rain will vary from 15 to 50 lb. Ludwig Schaller in "die Belastung der Baukonstruktionen durch Schnee," found the density of very dry clean snow to be 0.12, while that of very dry snow compacted by wind was 0.17; under other conditions (moisture, etc) it may become 0.41, 0.46, etc.

Relation of Latent Heat to Varying Degrees of Density. Determinations made on loose freshly fallen snow and also on packed snow indicate no difference in the latent heat. The latent heat naturally depends upon the mass of the snow, but has no connection whatever with volume *per se* and therefore only as far as mass concerns the density, will the latter determine the latent heat of the snow. The only important factor to consider in this connection is the water. With an increase in the percentage of the water in the snow, the density increases, and the latent heat decreases.

Amount of Dust Entrained in Snow as it Falls. As was mentioned above, the presence of foreign bodies in the snow will obviously depend upon the locality. The figures obtained show that the samples of snow collected at the roof of this laboratory contained from a trace to 0.05 % entrained dust. In every snowfall, after the snow has been falling for a short period, the atmosphere is freed of impurities, therefore the first part of the fall contains the greater part of the atmospheric dust. Hence the condition of the atmosphere is another factor to be considered.

Flush Test. This test was made in order to determine the approximate quantity of water necessary to flush a definite quantity of snow, and the following experiments were made. In the first case, 2400 grams of snow at 0.2° C (32.3° F) required 26 640 cu cm of water at 9° C (48° F) to flush it off; while in the second case 2350 grams of snow at 0° C (32° F) required 34 840 cu cm of water at 8.3° C (47° F) to flush it off. Ordinary tap water was used.

The ratio of water to snow is $\frac{28\,640}{2\,400} = \frac{148}{1}$ in the first case, and $\frac{11.9}{1}$ in the second case. These values have little significance, however, for a great deal depends upon the temperature of the water used.

Relative Weights of Snow and Ice. Some years ago a number of experiments were performed at Kingston, Canada, on the relative bulks of snow and ice. The results which are recorded (27) showed that the average temperature of 1 cu ft block of ice was − 18° C (0° F) and its weight was 57 lb. The block was allowed to melt at 11° C (52° F) and yielded ⅞ cu ft water or 1512 cu in weighing 54 lb. One cu ft of snow was then taken up and compressed. Its average temperature was − 7° C (19.5° F),

weight 63 lb, 14 ounces, and when melted at 11° C (52° F) yielded 1728 cu in water weighing 1021 ounces or 63 lb, 13 ounces.

Snow Melting with Portable Steam Boilers. Accepting the latent heat of snow at 144 B.T.U. the following data was compiled by Fetherston. It was assumed that the snow melting equipment would consist of portable steam boilers with flexible steam hose connections operated by laborers. It was also assumed that the water produced by the melted snow would run thru the gutters to the sewer inlets without freezing.

Table XV.—Data on Snow Melting by Portable Steam Boiler

HEAT REQUIRED PER POUND OF SNOW:	
Latent heat of snow	144 B.T.U.
Heat required to raise temperature from —6.7° to 0° C (20° to 32° F)	12 B.T.U.
Heat required to warm water 24° C (76° F)	44 B.T.U.
Total heat required to melt snow and run water to sewer basin	200 B.T.U.
WEIGHT OF SNOW PER CUBIC FOOT:	
Minimum weight newly fallen snow	5 lb
Ordinary weight newly fallen snow	12 lb
Weight of snow in trucks after handling	30 lb
Assumed average weight city snow	16 lb
SNOW MELTED PER POUND COAL:	
1 lb steam at 50 lb pressure contains	1174.00 B.T.U.
1 lb steam, no waste, will melt $\frac{1174}{200}$ or	5.87 lb snow
In portable boiler assume steam delivered per pound of anthracite coal	6.00 lb steam
Hence snow melted per pound of coal would be 6 × 5.87	35.22 lb snow
VOLUME OF SNOW MELTED PER POUND COAL:	
Assumed weight of snow per cubic foot	16 lb
Hence 1 lb coal (without waste of steam) will melt $\frac{35.22}{16}$	2.2 cu ft
AREA CLEARED OF SNOW BY STEAM FROM 1 LB OF COAL:	
Assume 6-in snowfall:	
1 lb. coal will melt, without waste of steam, $\frac{2.2}{0.5}$	4.4 sq ft
Assume 12-in snowfall:	
1 lb coal will melt, without waste of steam, $\frac{2.2}{1}$	2.2 sq ft
SPEED OF MELTING:	
Assume 70-h. p. portable boiler on wheels, allow 25 sq ft grate area and 12 lb of coal burned per sq ft of grate per hr or 300 lb coal per hr.	
Note: A 70-h. p. boiler on wheels will weigh 15 000 lb without water.	
Area cleared of snow per hour:	
6-in snowfall, 300 × 4.4	1320 sq ft, 146 sq yd
12-in snowfall, 300 × 2.2	660 sq ft, 73.3 sq yd
Volume melted per hour:	
300 lb coal × 2.2 cu ft	660 cu ft
Equivalent, cu yd	24.44
COST PER HOUR, 70-H. P. PORTABLE BOILER AND CREW:	
Coal at \$6.25 per ton = $\frac{300}{2000}$ =	\$0.9400
Horses, 4 at \$1.50 per 8-hr day	0.7500
Driver, 1 at \$2.50 per 8-hr day	0.3125
Engineer, fireman, 1 at \$4.50 per 8-hr day	0.5625
Laborers on steam hose, 2 at \$2.50 per 8-hr day	0.6250
Total, no fixed charges	\$3.1900

Cubic yards melted per hour, no steam wasted	24.4
Cost per cubic yard, original snow	$0.13

Application of Estimates to Conditions:

In Manhattan, Bronx and Brooklyn, the street area scheduled for removal was	22 410 446 sq yd
Number of 70-h. p. boiler hours required to clear this area:	
After 6-in snowfall	152 764
After 12-in snowfall	305 736
Number of 70-h. p. boilers working 24 hr per day required to clear snow:	
For 6-in storm, 6 days; For 12-in storm, 12 days	1 061
Cost of 1061 boilers at $700	$742 700
Minimum charge for interest, depreciation and storage per annum on above machines would amount to 15%	111 405
For average year, 4 storms of 6 in are removed, 576 hours per year boiler in use, thus the overhead per hour per boiler would be	18 cents

Actualities:

Allow 50% efficiency in the application of steam from hose on street, this is believed to be high, then the cost per cu yd of original snow would be 26 cents without fixed charges. With fixed charges 27.6 cents.

For comparison with truck haulage cost in Manhattan, 47 cents per cubic yard, the shrinkage in original snow would amount to at least 50%; thus cost of melting by steam would be 52 cents per cu yd without fixed charges, or 55.2 cents with fixed charges.

Coal Consumption of 1061 Boilers:

To clear 6-in storm in 6 days	22 915 tons
To clear 12-in storm in 12 days	45 860 tons

To keep the boilers supplied will require the delivery of 159.1 tons of coal per hr at 1061 localities in the city.

The Ashes to be Removed from Boilers:

After 6-in storm	2 292 tons
After 12-in storm	4 586 tons

Cost of ash removal not covered in estimates, but would amount to $1 per ton, and require the services of 382 city carts to remove ashes in 1 day after a 6-in storm, or 764 carts for 1 day after a 12-in storm.

Snow Melting by Steam Generated by Coke and by Naphtha Furnaces. During 1895 actual tests were made in New York City by C. D. Pollock under the direction of Commissioner Waring of the Street Cleaning Department.

Table XVI.—Snow Melting Test Data

STEAM SNOW MELTING TEST, SUNDAY, FEB. 17, 1895

Franklin St. basin, 140 ft east of Broadway, 8-hr test.

1	Engineman,	$3.50 for 10 hr	$2.80
1	Assistant,	2.25 for 10 hr	1.80
1	Boiler,	5.00 for 10 hr	4.00
1¾	Chaldrons coke at	4.00	7.00
2	Laborers at basin,	2.00 for 8 hr	4.00
3	Carts,	3.50 for 8 hr	10.50
			$30.10

Result: Melted 62 loads snow at 28½ cents per load. Does not include piling and loading.

STEAM SNOW MELTING TEST, MONDAY NIGHT, FEB. 18, 1895

Franklin St. basin, 9 hr test.

2 Engineers,	$3.50 for 10 hr	$6.30
1 Assistant,	2.25 for 10 hr	2.03
2 Boilers,	5.00 for 10 hr	9.00
3½ Chaldrons coke at	4.00	14.00
3 Shovelers at basin,	2.00 for 8 hr	6.75
6 Carts,	3.50 for 8 hr	15.75
		$53.83

Result: Melted 104 loads snow at 51.8 cents. Does not include piling and loading.

TEST OF CUNDELL'S NAPHTHA SNOW MELTING MACHINE

Night of Feb. 11, 2 blocks on Worth St., from Broadway to West Broadway.

Time of first machine, 4 hr, 57 min
Time of second machine, 4 hr, 12 min } Total, 9.15 hr.

20 Barrels naphtha used in 12¼ hr, 1.6 an hr at $3.75 per bbl:

Cost of naphtha per hr, $6 for 9.15 hr		$54.90
15 Laborers at $2.00	$30.00	
1 Foreman	2.50	
1 Engineer	3.50	
1 Assistant Engineer	2.00	
Cost of Labor, 8 hr	$38.00	
Cost of Labor, 9.15 hr		43.46
		$98.36

Two hundred and sixty-four loads of snow in D. S. C. carts were removed from Leonard St., between Broadway and West Broadway and Temple Court on night of Feb. 12th, 1895. Assuming the same quantity of snow to have been taken from Worth St., then the cost per load was about 37 cents.

Snow Melting by Electric Method. During Feb., 1914, the New York Edison Co., New York City, carried out a series of experiments on melting snow by electric power with the following results:

Table XVII.—Data on Snow Melting by Electricity

Test	Cu Yd Snow Melted	Elapsed Min	Time Hr	Electrical Data				Temperature of Discharged Water	Rates	
				Volts	Amps	Kw	Kw-hr		Cu Yd per Hr	Kw-hr per Cu Yd
1...	1	7.25	0.121	236	1017	240	29.0	....	8.3	29.0
2...	9	84.00	1.400	242	1100	267	345.3	75° F	6.4	38.4
3...	2	17.00	0.284	240	1010	avg 242	avg 68.7	39° F	7.0	34.3
4...	2	36.00	0.600	147	717	107	64.2	33° F	3.33	34.1

The snow which was melted weighed 35 lb per cu ft and it was estimated that with more efficient apparatus the current consumption could be reduced from ⅓ to ½. At a cost of 1½ cents per kw-hr, the charge for melting would approximate 45 cents per cu yd when dealing with snow weighing 35 lb per cu ft. The cost of gathering and handling snow would still have to be added to the melting expense, also the fixed charges. If hydrant water were not available for supplementing the normal flow of sewage, the use of electric melters might be advantageous, but it is doubtful if this method would compete with direct sewer disposal.

Snow Melting by Gas Heat Method. So far as known no extensive investigations relative to the practicability of utilizing gas heat for removing snow have been conducted in this country. In referring to this matter, however, Fletcher (22) states that: "The plan of melting by coal gas is absurd. Six inches deep of average snow, when

melted, becomes 1/6 in depth of water, 24 sq ft of which will weigh 62½ lb or 23.4 lb per sq yd. At this rate the snow on one mile of street 20 yd wide would, if 6 in deep, weigh 823 680 lb or 363¾ tons. The heating power of London gas is 660 units per cu ft and we may assume that 500 units could be utilized. It has been proven that 1 lb of snow at the freezing point requires 150 units of heat to melt it and raise the temperature of the water obtained to 4.4° C (40° F) and this effect would be produced on 3⅓ lb snow by the consumption of 1 cu ft of coal gas. From the above data, it will be found that to melt the snow in the assumed mile of street would require the consumption of 247 000 cu ft of gas, costing at 3 s ($0.73) per 1000 cu ft, a little over 37 lb, or at the rate of 3256 lb per sq mile. Even if we were to assume that the cost of gas and labor was not prohibitive, the fact that the ground itself is usually colder than 0° C (32° F) must be considered, and the ground would also have to be warmed or a thin surface of glassy ice would remain after the snow was removed; this would also condemn the project."

Steam Pipes Under Sidewalks and Roadway. There has been suggested the installation of steam pipes under the sidewalks and roadway, connected with central heating plants.

General Considerations. No estimate is available of the cost of such an installation. The installation of a system of heating which would insure the temperature of the pavement remaining at say 27° C (80° F), while the temperature of the air was as low as −18° C (0° F), would serve to prevent any accumulation of the snow and the snow problem on city streets would be solved in an ideal way. Some such arrangement may ultimately be used on certain streets in large cities, but the difficulties in the way of such a scheme are many. It would be necessary to install one or more mains, depending on the width of the street, with laterals not more than 4-ft centers from house line to house line. This would mean that either the entire pavement would have to be removed or that it would be necessary to wait until the street was repaved before installation. With such a network of pipes on the surface, the difficulty of installing new underground structures is apparent. The question of taking care of the large quantity of condensed steam would also be a problem in itself. As there is scarcely a building in the center of a city which is not equipped with a heating plant, some arrangement or legislation might be had to compel property owners to supply with steam the pipes directly in front of their properties, this to be supplemented by the heating plants controlled by the city. The cost and impracticability of installing such a system on a large scale, on account of the numerous difficulties to be encountered would not seem to warrant serious consideration, but in 1950 or later, when there is a possibility of dreams of the ideal city becoming a fact, this method is recommended for consideration in connection with future city planning.

Portable Car Equipped with Steam Pipes. The Penn. Co. has been using several snow melting devices on their Philadelphia Terminal Division. One of these devices might be made particularly applicable to municipal work; the others are peculiar to railroad work, such as the melting of snow in switches with burning oil, and the disposal of snow in snow melting pits located in their yards. Also a device on a locomotive by which the snow is blown away from the tracks with live steam sent thru a pipe located between the wheels and near the tracks, but the idea of equipping a car with steam pipes for melting snow is one which is worthy of attention for municipal work.

Method of Use. The R. R. Co. uses a gondola car, the inside dimensions being about 38 ft 8 in in length by 9 ft 3 in in width and 3 ft 9 in in depth, about 1 ft below the top of the car being a false bottom forming a pan, which is used for the steam pipes and for storing hot water. The steam pipes are of various lengths and are open at the ends. This arrangement distributes the steam directly over the entire pipe. The first snow is melted by the steam and in a short time the accumulated water is boiling. The snow is then melted by the boiling water. In the center of the pan is a small manhole, 11 in high, thru which the water overflows to the lower part of the car which is about 2 ft 6 in in depth, and is used for the storing of the accumulation of snow water. The amount of snow that can be melted in the car before letting the water out is equivalent to approximately 25 carloads of the type of car generally

used by them for this purpose, depending somewhat upon the compactness of the snow. With 20 men this car has been filled with water three times a day of 10 hr. The water can be dumped at any drain or pit, or when the ground is frozen, at any point where it will readily drain away. A single car has a distinct advantage over a long train in congested districts. It also frequently happens that a car can be emptied at points where there is snow to be loaded. In this way more snow is being disposed of while the car is emptying itself. Naturally, the best results are obtained by handling the snow while it is new and before too much dirt is mixed with it. The car has been in use for two winters and in 1916–1917 was used continuously after each snow storm until the accumulation of snow had been removed. During all the snow storms of the 1916–1917 winter the R. R. Co. did not haul one shovelful of snow from the Penn. Terminal yard and considering the actual necessity of keeping these tracks practically entirely clear of snow, particularly around switches, the R. R. Co. feels that this shows conclusively the advantages of the various melting devices which they are using.

16. Administration and Organization of Snow Removal

General Organization. As in any other similar character of work it is necessary to have a very definite order of procedure in the general organization under which the work is performed, and the following details of such an organization in Philadelphia, under the direction of the author as Chief of the Bureau of Highways and Street Cleaning from 1912 to 1917, will give a general idea of some of the essential factors necessary to properly control this work:

In Philadelphia the snow removal and disposal work was performed by the following regular and emergency forces: (1) Emergency snow re-

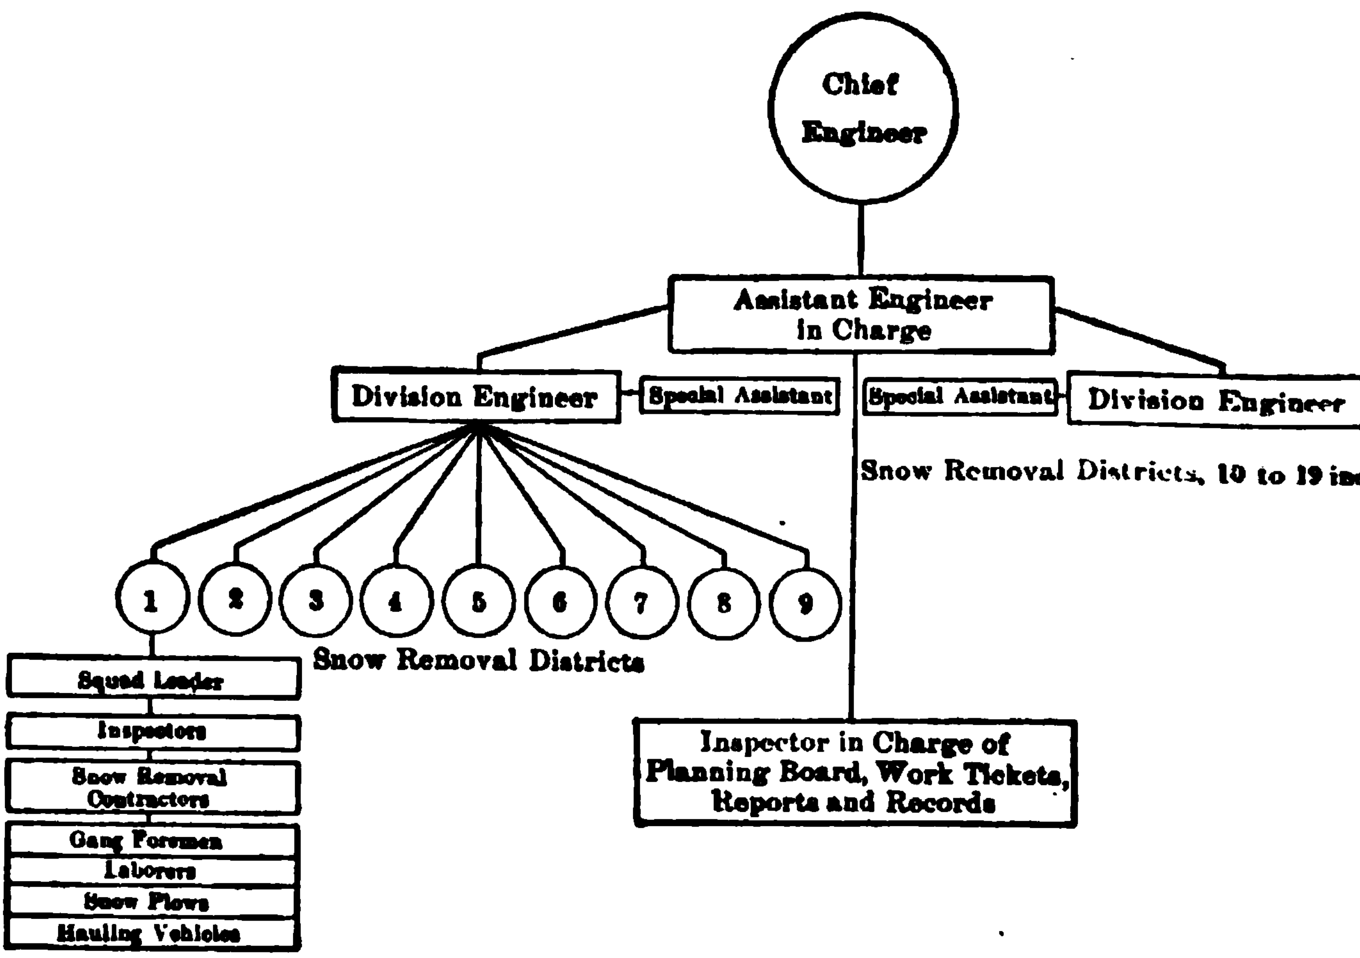

Fig. 5. Organization Chart of the Routine Snow Removal Work in Residental and Outlying Business Sections of Philadelphia

moval laborers and contractors' forces; (2) regular street cleaning forces; and (3) regular municipal labor forces.

The cleaning of snow and ice from the entire area of highways in the central business section, which is divided into 19 districts, was done by the emergency snow removal contractors' forces, emergency laborers and

the regular street cleaning and municipal labor forces under the direct supervision of the Chief Engineer assisted by a provisional organization composed of special assignments from the entire engineering and inspection force. That portion of the snow removal work which was performed jointly by the regular street cleaning forces and the municipal labor forces under the direct supervision of the district engineers and their regular subordinate organizations, included the removal of snow and ice from highway crossings, gutters, sewer inlets and the vicinity of fire hydrants thruout the city; and, after this work was finished the cleaning of the entire areas of certain selected highways in the important business sections in the several respective districts. A large force was also employed opening up the suburban and country roads, where the drifts often completely block traffic. The organization details of both the regular district forces and the provisional central forces are indicated respectively on charts, Figs. 5 and 6.

The Snow Alarm or Mobilization of the Snow Removal Forces. The main idea in a snow removal organization is preparedness. The snow alarm, or preparedness in the work of snow removal as it was generally termed in Philadelphia was an innovation introduced by the writer when Chief of the Philadelphia Bureau of Highways and Street Cleaning and was operated from 1912 to 1917. The conception and operation of the snow alarm in Philadelphia was one of the unique improvements which resulted in greatly benefiting the community.

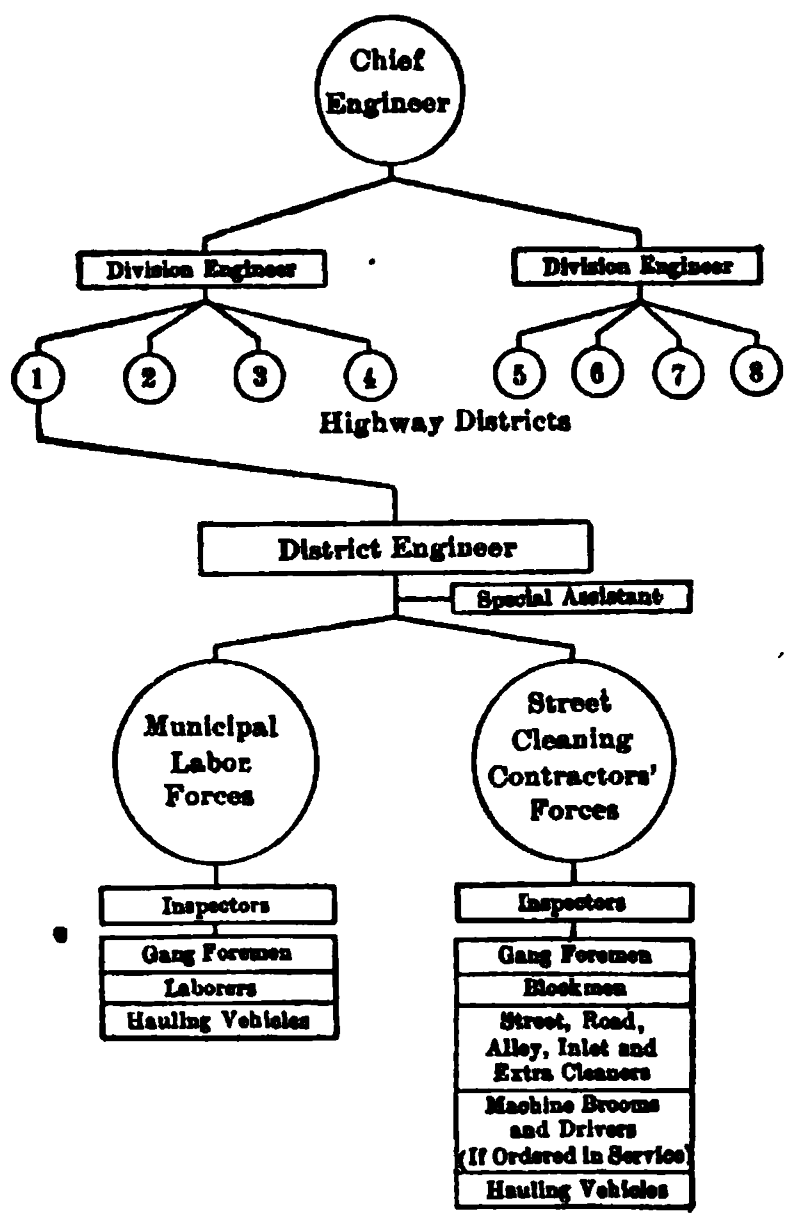

Fig. 6. Organization Chart of the Emergency Snow Removal Work in the Central Business Section of Philadelphia

Details of Operation of Snow Alarm. At any hour of the night, as soon as the snow started to fall the Electrical Bureau in the City Hall notified the Chief Engineer of the Bureau of Highways and the several division and assistant engineers in charge of snow removal work, by telephone in their respective homes. The engineer in general charge of snow removal work lived in the central part of the city and when weather conditions necessitated was in constant communication with the Weather Bureau and the Chief Engineer of the Bureau of Highways. This engineer also kept an hourly record of the thermometer and barometer readings, the depth of snow, direction of wind, so that an exact history of every storm was at hand. The snow alarm or the order to mobilize the forces and begin snow plowing or removal operations was given by the Chief Engineer of the Bureau. This action was based on the likelihood of the depth of the snowfall of 2 in or more, and the existing and predicted weather and temperature conditions. In giving the alarm the Chief Engineer telephoned his instructions to the assistant engineer in charge, who immediately transmitted these instructions

to the several division engineers. The division engineers in turn communicated with their special assistants, who immediately reported at the main office. The issuance of instructions to all concerned occupied but a comparatively short time as the Electrical Bureau handled all calls in connection with a snow alarm as emergency calls.

The inspectors assigned to the snow plows were first called to duty. These inspectors reported at the stables and garages where the respective plows to which they were assigned were kept. Each inspector had the names and addresses of the plow operators and it was his duty to see that the contractor or his representative assigned to the stable or garage made immediate arrangements to get these men to report to the stable. Arrangements were also made with the Police Department to aid the inspectors in reaching the men and upon request patrolmen were assigned to this duty. When the plows were ready to start work the inspectors notified the main office and the plows were kept in readiness until ordered to work. This scheme put the department in control of the plows at the beginning of the storm.

As soon as the indications pointed to a continuance of the storm the entire snow-fighting equipment was ordered out, upward of 1000 telephone messages being sent out to various parts of the city calling out squad leaders, inspectors, drivers, teams, laborers, and officers in the various police districts who aided in getting out the men. This army of laborers and teams kept constantly at work in day and night shifts, plowing, shoveling and dumping the snow into sewer manholes and into the Delaware and Schuylkill Rivers. Every man in the snow removal organization had a particular function assigned to him. For instance, each dump inspector knew just what to do when he got there; the driver of every team knew where he was to report, at what point he was to start to load, and at what sewer manhole or wharf he was to dump his loads, and there was no confusion. Fighting the snow at night during some of the storms during the period of 1912 to 1917 was no easy task for the engineers assigned as squad leaders, the inspectors and the laborers, and it required the constant presence of the Chief of the Bureau and his principal assistants to encourage the men and stir up the necessary enthusiasm to keep the work going.

The main idea in the Philadelphia snow alarm was simply the practical application of the principle of preparedness in the work of snow removal. The organization had been instructed in the methods that under the circumstances would seem to be best adapted to prevent interruption to traffic during and after a snowfall. During the daytime the mobilization of the snow fighting forces was an easy matter as compared with turning out this force at night. It is practically impossible to get a great number of laborers to work at night during a very severe storm, and to offset this great stress was laid on the use of the snow plows to keep the streets open to traffic. Whenever the storm occurred in the daytime or at night when the weather conditions were not too severe considerable of the work was performed by flushing, sweeping and shoveling snow into sewer manholes and inlets. This method could not be depended upon in a heavy storm as it would be practically impossible to get a sufficient labor force to work to keep the streets open to traffic, and it is for this reason that the plows should be kept constantly at work plowing the snow to the side of the street during the progress of the storm. This keeps the streets open to traffic when difficulty is experienced with the labor situation. There never should be very great difficulty in getting laborers and teams in the daytime or at night to load the snow piled at the side of the street into the wagons and haul it to the dumps. It is difficult, however, to secure sufficient laborers to dispose of the snow by shoveling it into sewer manholes. This feature of the work should be simply supplemental to the main feature, which is the use of the plows to keep the streets open to traffic, and after several years' experience with this method it would seem good policy to have on hand snow plows and place the main dependence upon them, as it takes very little time to get them on the work and it is possible to keep them at work at all times, even during the most trying conditions. When the snow is plowed to the side of the street it simplifies loading it in wagons for disposal.

Availability of Employees for Duty. All employees assigned to snow removal work should be on duty at all hours of both the day and night during the entire winter season, subject to call at any hour of the day or night to report for the routine performance required by their respective assignments. When the weather conditions are such that snow may be expected the employees should be required in case of absence from the scheduled call address, to make suitable arrangements for receiving

immediate notice of any order to report for duty that may be sent them and to hold themselves in readiness for a subsequent call. Employees should be required to promptly advise the assistant engineer in charge of snow removal work of any change in their call addresses or telephone numbers.

Arrangements for Calling Snow Removal Forces to Duty. Both the division engineers and the district engineers should be required to maintain a complete roster of both the regular municipal labor and street cleaning forces and the emergency snow removal forces under their respective jurisdiction. This roster should contain the name and call address and telephone number by which each member of the force may be reached, and also the numbers of the police districts in which their homes are located. Each of the municipal gang labor foremen should be made personally responsible for the notification and reporting on the work of a selected number of the municipal labor employees living in his locality. The inspectors and gang foremen should, when weather conditions make it necessary or advisable, hold themselves in readiness to be called, but need not, however, telephone to the office. When an employee cannot be reached by telephone the police district in which his home is located should be requested to notify him by sending a policeman to his home. After proper notice is given the contractors should, however, be responsible for the prompt reporting of their forces on the work in accordance with the pre-arranged assignments.

Duties of Division Engineers. The division engineers should be required to exercise a vigorous supervision over both the emergency and the regular district snow removal work under their respective supervision, and to see that the work is conducted in such a manner as to satisfactorily meet the prevailing conditions. The amount of time spent by the division engineer in either the office or supervision of the work should be governed entirely by the current requirements of the work, but all work of a routine nature should be assigned to their special assistants.

Duties of Special Assistants to Division Engineers. The special assistants to the division engineers should be instructed to report promptly at the main office when the weather conditions seem to indicate that a snowfall of 2 in depth or more will occur, and on arrival at the main office they should immediately report their presence to their respective division engineers either verbally or by telephone. The special assistants should be provided with a copy of the organization schedule and the call addresses of all of the employees and contractors assigned to snow removal work, the planning board equipment, hauling tickets and report forms. When instructed to order out the forces they should transmit the instructions to the several squad leaders assigned to their respective divisions. The special assistants should be required to keep in close touch with the U. S. Weather Bur. in order that there may be a knowledge of any forecasted weather conditions that may influence the manner in which the work may be prosecuted.

Duties of Squad Leaders. After receiving notice to begin operations the squad leaders should be responsible for the prompt reporting on the work of the inspectors and the contractors' equipment and forces assigned to their squad and should see that the snow removal work in the respective districts is promptly begun and performed in an effective and systematic manner and that the assistant engineer in charge is kept advised of the progress of the work by making informal verbal or telephone reports at hourly intervals during the day and by submitting a formal report summarizing the performance for each day. Prior to the advent of snow, however, the squad leaders should be required to fully acquaint themselves with the physical and traffic conditions existing in their respective districts, the location and character of the assigned dumping places, the quantity and character of and the storage locations of the contractors' equipment, and the names and call addresses of both the contractors and inspectors assigned to their respective squads. They should be required to see that their inspectors and the contractors are thoroly instructed in their respective duties to insure that there will exist no possibility of misunderstanding concerning any detail of the work. The squad leaders should also be required to provide themselves with the following forms and data: Specifications, schedule of streets and limits included in each district, snow removal map, organization schedule and call addresses of employees and contractors reporting to them on snow removal work, dumping and loading work tickets and daily report forms.

Duties of Inspectors. The inspectors should be in constant and direct supervision of the work and be required to see that the snow is promptly and properly plowed

into windrows adjacent to the curb and shoveled into suitable piles at such locations as they may designate, and then promptly hauled away. The inspectors should be required to measure and calculate the cubical carrying capacity of all vehicles engaged in hauling and to see that these vehicles are fully and properly loaded and discharged at the assigned dumping places, and to issue work tickets therefor. They should also be required to see that any equipment hired at per hour rates is kept constantly in effective operation.

Traffic Requirements. It should be required that snow removal work be conducted in such a manner as to cause the least possible obstruction or inconvenience to traffic. The inspectors, upon beginning operations, should explain to the nearest traffic policeman just what work is to be done and the proposed manner of doing it, and request his active coöperation toward its efficient performance. The traffic policeman should be authorized to permit the work, if this be necessary to proceed, in a direction opposite to the direction of traffic if this will not cause serious interference.

Maps, Instructions and Record Forms. To assist in the efficient operation of the snow removal work the following instructions and forms should be provided:

Maps, indicating by colors the highways included in each of the central snow removal districts and the nature and exact location of the snow dumps. A properly mounted copy of the map serves as a planning board upon which the progress of the work is shown graphically by the means of glass-headed pins of various colors and sizes.

Planning Board, consisting of a mounted snow removal district map legend and a graphic progress record with glass headed pin indicators of various sizes and colors.

Detailed Instructions, which definitely indicate to the assistant engineers and inspectors supervising the snow removal, the nature of the work to be done and the methods to be used in its performance and their duties in connection therewith.

Organization Schedules, indicating the name and the call address and telephone number, and the assignment of each employee detailed to snow removal supervision.

Hauling Work Tickets of distinctive colors respectively for loading and dumping.

Ticket Issue Records.

Current Status of Work Records.

Squad Leaders' Daily Reports.

Squad Leaders' Daily Report Summary.

Snow Removal District Maps. Snow removal district maps, a copy of which should be issued to each squad leader, contains for each of the several emergency snow removal districts in the central business section of the city, the following data: The highway included in each district, indicated by color; the name of the squad leaders and contractors and the exact locations and characters of the dumping places. The map further indicates the dumps specifically assigned for the use of each of the several district contractors.

Planning Board. In order to provide a better means of directing the emergency snow removal operations in the central business section than would be possible thru the study of records, a planning board system should be installed by which it is possible to visualize with a minimum of effort the current status of the work in each district with respect to character and quantity of force employed and the progress of the work. This equipment should consist of a mounted copy of the snow removal map supplemented by a legend, graphic progress record, Fig. 7, and indicators consisting of glass headed pins of various colors and sizes. The map indicates the area of highway from which snow is to be removed that is included in each district and also the location of the dumps. With the pin indicators it is possible to indicate at which dumps and other locations inspectors are either on duty or needed and if a dump is in service. By hatching and cross hatching the colored portions of the map it is possible to indicate

respectively what relative postion of the streets have been plowed or entirely cleared of snow. By inserting the proper kind of indicators in the proper space on the graphic progress record it is possible to indicate for each district the numerical strength and character of labor and equipment and also to show if these forces are assembled, ordered on duty, or if they are working or have suspended operations. With this equipment, which can be posted in a few seconds, it is possible to determine at a glance, information which, if in the form of written records, would require considerable time and even then could not be visualized.

Detailed Instructions. For the purpose of uniform guidance each member of the engineering and inspection forces assigned to the supervision of snow removal work should be furnished on or before Nov. 1st of each year, with a set of detailed instruc-

Fig. 7

tions outlining their respective duties and indicating the manner in which the work is to be performed. These instructions should remain in force until formally amended or recalled.

Schedules of Proposed Work. On or before Nov. 1st of each year the several division engineers and district engineers should each be required to prepare and submit to the Chief Engineer for approval a complete schedule of the proposed snow removal operations in the territory under his respective jurisdiction during the coming winter, together with an estimate of the probable force and equipment requirements and a statement of the proposed assignments of both the emergency snow removal contractors' forces and the regular street cleaning and municipal labor forces in connection with this work. In this schedule there should be included a definite assignment for each individual assistant engineer, inspector, foreman and gang and a summary of the character, quantity and sequence of the work proposed to be performed. After the approval of these schedules the several division engineers and district engineers should be required to immediately acquaint their subordinates with the exact nature of their respective assignments and duties and to further review this matter with their subordinates whenever it is thought to be necessary.

Work Tickets. The responsibility for the safeguarding and issuance of the loading and dumping tickets, Fig. 8, should be centralized in one person in the main office, who obtains a receipt on the ticket issue record for all tickets issued, and upon the return of the used tickets and ticket packet stubs checks these against the receipts to insure that no tickets are unaccounted for. The inspectors should be required to carefully guard the tickets in their possession so as to prevent loss or unauthorized use, and in no case should the inspectors be permitted to sign these tickets in advance of their actual issuance. All inspectors' signatures should be signed in either indelible pencil or ink, and the date of issuance indicated on all tickets and also the serial number of the ticket for which it is exchanged. The squad leaders and inspectors should be required to see that at all times they are supplied with a sufficient number of tickets

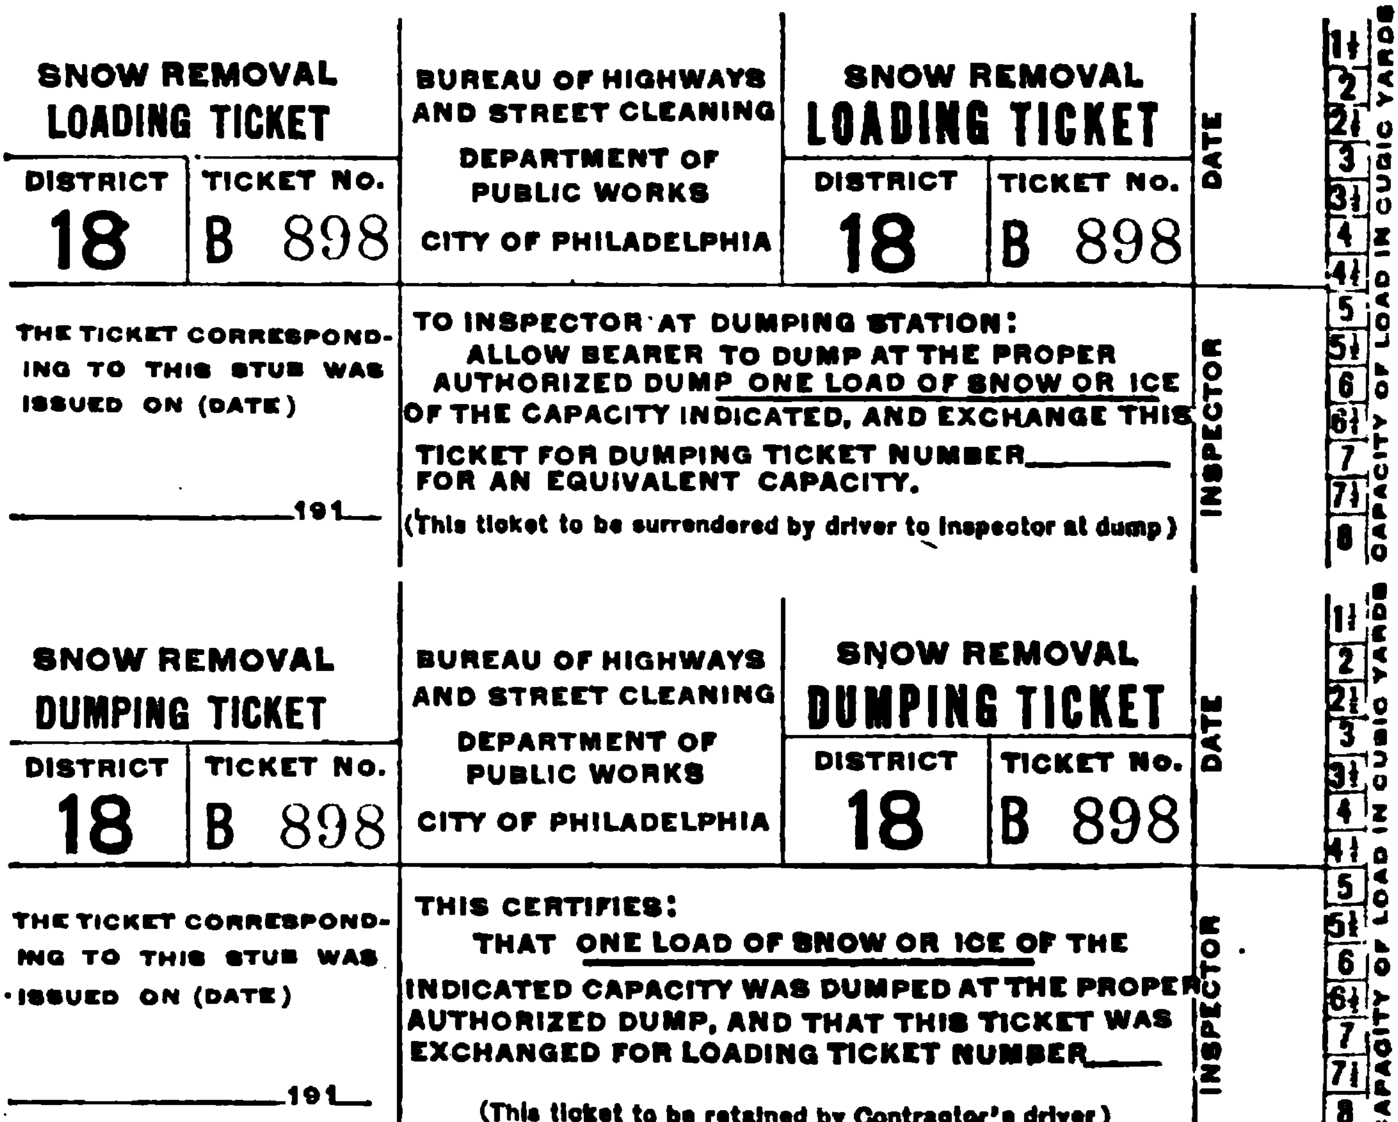

Fig. 8

to meet the requirements of the work. All tickets and stubs should be required to be promptly returned to the office at the termination of the inspectors' period of duty.

Current Status of Work Record. The separate special assistants should be required to maintain for each snow removal district a permanent record of the current status of the work compiled from the informal hourly reports telephoned or made verbally to them by the squad leaders. Upon this report should be recorded from the informal reports made by the squad leaders for each specific district, the date and hour of the report, the force of labor and equipment at work, the progress and condition of the work and the name of the squad leader making the report. The entries on these reports are intended to constitute a complete historical record of the current progress of the work.

Squad Leaders' Daily Reports. The inspectors should be required to submit formal daily reports relating to snow removal work. Any information that an inspector has to report should be communicated to the squad leader to whom he reports. The squad leader should be required, however, to submit to the assistant engineer in charge a daily report. This report should contain a record for a specific district of the time that both the plowing and removal forces were ordered to report for duty, and the

times of their beginning and quitting work, the name and limits of each highway upon which work was done and the character and quantity of work performed, together with the number of both loading and dumping tickets issued, a record of the working quantity hours worked and total force, hours for each class of labor and equipment employed, the names, nature of assignment and working hours of inspectors, the contractor's name, weather and temperature conditions, and any other pertinent information relative to the prosecution of the work that should be of record. The reports should be mailed, or delivered in time to reach the main office on or before the morning of the business day following the date of the report. At the expiration of 1 hr after arriving on the work, squad leaders should be required to report by telephone to the special assistant the general status of the work and to subsequently report thereafter in the case of any important changed conditions or irregularities in the performance of the work.

Summary of Squad Leaders' Daily Reports. Upon the receipt of the several squad leaders' daily reports for work in connection with each separate storm there should be compiled a summary of the reports. This summary should indicate for each district and for the day that the work was in progress, the character and quantity of the forces employed and the number of loads and cubic yards quantities of snow removed. From this data can be determined the total quantity of snow removed and both the actual and contract unit and the total cost of the work.

SECTION 23

CAR TRACKS AND PIPE SYSTEMS

BY

GEORGE W. TILLSON

CONSULTING ENGINEER

TO THE PRESIDENT OF THE BOROUGH OF BROOKLYN,

NEW YORK CITY

CAR TRACKS

1. General Conditions Affecting Car Tracks

Development of Traffic. The problem of constructing street-car tracks in a satisfactory manner in paved streets has been one which municipal engineers in charge of pavement construction have been trying to solve for many years. In the early days of street-railways, when the streets were paved with cobblestones and the cars used were small and drawn by horses at a speed of 5 or 6 miles an hr, this question was not so important; but in the present time of improved pavements, of rubber-tired bicycles and motor-cars, used both for pleasure and for business, and with street-cars weighing from 25 to 35 tons, propelled by electricity along heavy traffic streets at a speed of from 8 to 15 miles an hr, the importance of good and smooth track construction, both to the general public and the street-car companies themselves, can hardly be overestimated.

Factors Influencing Design. It is an undoubted fact that the construction in the street-car area of a pavement different from the pavement itself is a detriment, both because it is difficult to maintain the two constructions at an even surface and because they must be of different degrees of hardness, and consequently the wear from traffic must be uneven. Of all the constructions built into a street, the street-car track is probably more difficult to deal with than any other. If the track were owned and the railroad operated by the municipality the problem would be simpler, but such is not the case in the United States. Altho a street-car track in a paved street is recognized to be an evil, it is also recognized to be a necessary evil, for, as cities develop and grow, it is absolutely necessary that

their inhabitants have means of transportation, not only from place to place in the cities, but from their centers to the outskirts and suburbs where most people live. The question of street-car track construction is different from that of the ordinary railroads. Steam cars generally run on their own right-of-way, making stops only at long and stated intervals, and the tracks can be constructed in such a manner as will give the best results as regards economy of construction and maintenance, with no regard for the wishes of others except at street or road crossings. In paved streets, however, the problem is different, and is one that taxes to the utmost the municipal engineer. He recognizes, however, that the tracks must exist and that he must get the best results with them located in the street. The problem, too, is complicated by the fact that the street-car companies control almost entirely the space occupied by them; that is, under the law, in accordance with their individual franchises, they must construct and keep in repair the pavement within and generally 2 ft outside of the rails. The matter of track construction, too, is different at the present time from what it was 40 or 50, or even 20 years ago, on account of the changes, not only in the pavement, but in the cars themselves. Street-cars run, it must be remembered, not only for the benefit of the corporations owning them, but also for the travelling public, and whatever can be done to facilitate rapid transportation of the public is a benefit to one as well as to the other, altho in a different way. Probably at least 40% of all the business men in the average American city of more than 100 000 inhabitants depend more or less upon the street-cars for their conveyance every day. The street-railway authorities and the officers of the city in which they operate often differ considerably in their ideas as to what is the proper track construction. The street-car companies are interested in performing their work economically, and a construction that will allow their rolling stock to be operated with the least amount of wear and tear, and will cost least for original construction and for maintenance, is what they desire. On the other hand, the officials of the city are not interested either as to first cost or the cost of maintenance, except as to how the repair work on the tracks interferes with the general public.

Use of Tracks by Vehicles. In the early days of street-car track construction, when the pavements outside the track area were rough and uneven, vehicular traffic on the street often took to the street-car tracks in preference to the pavement, and interfered to a great extent with the operation of the cars. The companies sought in every way to prevent this, to such an extent indeed that sometimes it seemed as tho they laid a type of rail that should be an obstruction to traffic. With the old rough stone pavements the actual form of the rail, even if naturally obstructive, did not add very much to the general roughness of the street, but in more recent years, with the advent of smooth pavements, the street-car companies have recognized that their tracks should be constructed in such a way that they will present as little obstruction to street traffic as possible; and, as the pavements are smooth and also kept in better condition, there is not the tendency of vehicular traffic to take to the tracks as existed heretofore.

The Ideal Form of Construction, no matter what its exact type, seems to be one in which the track is practically a part of the pavement construction, and not a separate and definite part of the work. The work each has to do should be studied and considered as a whole. The time of the probable renewal of each should be taken into consideration, and the types so designed as best to accommodate the renewals of each. This

however, is not always practicable, as it often happens that the pavement and the railroad tracks are constructed at different times, when the one last constructed must be adapted as well as possible to the requirements of the former. With the modern and more permanent type of pavement, however, street-car companies recognize the importance of doing their track work, if possible, whenever a new pavement is laid. This is often convenient, from the fact that new types of larger and heavier cars are being introduced, so that new track construction may be necessary. Street-car companies, however, as well as individuals and others, must be governed by financial conditions in carrying out their work, and it generally is a serious proposition for the street-car companies to keep the pavement in their track areas in good condition. It must be acknowledged, however, that the street-car companies thruout the country are recognizing their obligations and meeting them in such a way that conditions in respect to their pavements are improving rapidly, so that in a comparatively few years the pavement in the track areas should be as good as that outside.

2. Franchise Requirements Relative to Car Tracks

Life of, and Payment for, Franchises. The question of the proper payment to be made municipalities for the use of their streets and highways for the operation of street-cars has never been definitely settled. In some cities it is arrived at by the companies paying a certain amount to the city, sometimes based upon the total receipts or the number of passengers carried, or sometimes a lump sum is determined upon in advance. In a new country, where cities are growing rapidly and the matter of transportation is important, property owners are often so anxious to obtain street-car conveniences that they are willing, not only that the company should have a franchise for nothing, but will make certain payments to the company as an inducement for early construction. This for the time being is proper action, as the cars must be operated for a considerable length of time before they will be remunerative from the stockholder's standpoint. On account of this feeling, many franchises have been given for small remuneration that have proved immensely valuable in a comparatively few years. In fact, nearly all of the older street-car franchises in the country were given in perpetuity, and for small sums. In recent years, however, the question of the value of the franchise has been pretty thoroly worked out, and in many cities franchises are given for limited periods only.

American Practice. It can be said, as a general proposition, that the pavement requirements in America of street-railway companies are to lay and maintain the pavement between their tracks and rails and 2 ft outside on each side with such material as is determined upon by the city authorities.

In New York City, for instance, the law provides that no franchise shall be given a corporation, for any purpose, for more than 25 years. In a franchise recently given to the Manhattan Bridge Three-Cent Line, to operate in New York City over the Manhattan Bridge, from approximately the Hudson River in Manhattan to the station of the Long Island Railroad at Atlantic Ave., in Brooklyn, it was provided: "The Company shall pay to the City for the privilege hereby granted the following sums of money: (1) The sum of $15 000 in cash within 3 months after the date on which this contract is signed by the Mayor, and before anything is done in exercise of the privilege hereby granted; (2) during the first term of 5 years an annual sum which shall in no case be less than $4000, and which shall be equal to 3% of its gross annual receipts if such percentage shall exceed the sum of $4000; during the second term of 5 years an annual sum which shall in no case be less than $7000, and which shall be equal to 5% of its gross annual receipts if such percentage shall exceed the sum of

\$7000; the gross annual receipts mentioned above shall be the gross receipts of the Company from all sources within the limits of the City; (3) for the use of the tracks owned by the City upon the Manhattan Bridge and the approaches thereto, the sum of 5 cents for each round trip or the sum of 2½ cents for each single trip of each and every car operated upon the bridge." This is in addition to laying and maintaining the pavement between its tracks and for 2 ft outside on each side.

Dorchester, Mass., Franchise. In 1854 an act was passed by the Massachusetts Legislature incorporating the Dorchester Avenue Railway Co. This was one of the first franchises given for a street-railway. The company was required to keep in repair the whole of the bed of any road in the town of Dorchester in which it might lay tracks. In the following year the act was amended by the repeal of this particular clause and the substitution of a provision that required only that part of the road occupied by the tracks be kept in repair, and defining that portion "to be the space between the rails and so much on each side thereof as shall be within a perpendicular let fall from the extreme width of any car or carriage used thereon, being the space from which public travel is excluded during the passing of said car or carriage."

Baltimore, Buffalo and Brooklyn Requirements. In Baltimore, Md., the street-car companies pave and keep in repair the space between their tracks and 2 ft on each side. In Buffalo, N. Y., different conditions exist in regard to the paving requirements by the different companies, but, in general, the maintenance of the street between the tracks and 2 ft outside is required, the pavement to be of a kind specified by the city. In 1895 a bill was passed by the Legislature of the State of New York providing that one-fourth of the cost of repaving any street in the then City of Brooklyn in which a street-railway was operated should be assessed against the company owning such tracks. Many streets were paved under this law, but no great amount of the tax was collected from the street-car companies. In Brooklyn, N. Y., the original franchises of the different companies generally provided for the repaving of the space between the tracks and rails and 2 ft outside with water stones (known as cobblestones). The companies, however, now generally accept the proposition that they are required to lay a good and substantial modern pavement.

New York State Railroad Law. In 1892 the Legislature of New York passed a law, known as the Railroad Law, a portion of which reads as follows: "Every street-railroad, so long as it shall continue to use any of its tracks in any street, avenue, or public place in any city or village, shall pave and keep in permanent repair that portion of such street, avenue, or public place between its tracks or rails of its tracks, and 2 ft in width outside of its tracks, under the supervision of the proper local authorities, and whenever required by them to do so, and in such manner as they may prescribe. In the case of neglect of any corporation to make these pavements or repairs after the expiration of thirty days' notice to do so, the local authorities may make same at the expense of such corporation." This law has been interpreted to relate to railroads in cities and towns where no special provision was made in the original charters, or where there was any question as to the liability of the railroad to keep the pavement in repair.

Chicago Ordinance. In 1907 the question of the treatment of the street-railway system of Chicago was taken up and a special ordinance passed regulating their construction. The ordinance provided that the tracks should be laid with modern improved rails of the grooved type, weighing not less than 129 lb per yd, and that the rails should be laid upon concrete beams, wooden ties, steel ties, cast-iron chairs, or some other form of first-class modern approved street-railway track construction; the foundation to be of concrete, crushed stone or other ballast material which in the judgment of the Board of Supervising Engineers should best suit the conditions of soil and drainage. As regards the maintenance of the space in the streets occupied by the tracks, it provided that the company should fill, grade, pave, keep in repair, sweep, sprinkle and keep clean and free from snow 8 ft in width of all streets and public ways, or portions thereof, occupied by it with a single-track railway, and 16 ft in width of all streets and public ways, or portions thereof, occupied by it with a double-track railway. It also provided that when the city paved the street in which car tracks were located with an improved pavement, the company should pave its area as given above with a granite block pavement which was described in detail, making a modern granite pavement. It was provided, however, that in any ordinance ordering the paving of streets the company should be required to pave its area with the same material specified for the remainder of the street.

Detroit, Indianapolis and St. Louis Requirements. Detroit, Mich., has what are known as 3 and 5-cent car lines. In streets where the former lines are operated the city paves the entire area, but in streets where the 5-cent lines are operated, the street-car company paves and maintains its area. In Indianapolis, Ind., a readjustment of the terms of the original franchise of the street-railway company was made in 1878, when a provision requiring the road to repave between its tracks was changed so as to read, "repair between its tracks." In St. Louis the companies are required to pave within the tracks and 12 in outside of the rails, with a material that is approved by the city authorities.

Philadelphia Practice. In 1892 the street-railways of Philadelphia changed their power from horses to electricity, and an agreement was entered into between the companies and the city authorities by which the companies agreed to pave and maintain the streets thru which they operated from curb to curb. The streets of Philadelphia are narrow, and in most cases only one track is operated in a roadway, so that a large amount of street mileage is occupied by the street-car companies. More recently, however, an arrangement has been made between the railroad companies and the city by which the former pay to the latter $500 000 annually, and that sum is accepted as fulfilment of the companies paving obligations. From one standpoint this seems a very desirable arrangement, as it obviates entirely any dispute between the city and the companies as to what repairs are necessary, and allows the city to proceed with and make repairs without serving any notice on the companies. If the amount paid is reasonable, it would seem to be the most satisfactory arrangement possible.

In Toronto, Canada, the street-car tracks are owned by the city, but, under an arrangement made in 1891, they are operated by the Toronto Railway Co. In the agreement made between the city and the company it is required that the purchaser shall maintain the ties, stringers, rails, turnouts, curves, etc, in a state of thoro efficiency and to the satisfaction of the City Engineer, and shall remove, renew, or replace same as circumstances may require and as the City Engineer may direct. When a street upon which the tracks are now laid is to be paved in a permanent manner on concrete or other foundation, then the purchaser shall remove the present tracks and super-structure, and repave the same according to the best modern practice, by improved rails, points, and substructure of such description as may be determined upon by the City Engineer as most suitable for the purpose. In the event of the purchaser desiring to make any repairs or alterations to the ties, stringers, rails, turnouts, curves, etc, on paved streets, the purchaser shall repave the portion of the railway so torn up at his own expense. When the purchaser desires, or is required, to change any existing tracks or substructure for the purpose of operating by electricity or other motive power approved by the City Engineer and confirmed by the Council, the city will lay down permanent pavement in conjunction therewith upon the track allowances as herein defined to be occupied by said new tracks and substructures. This at first applied only to existing main lines and thereafter to branch lines or extension to main lines and branches. Under the terms of the agreement the company pays the City Treasurer $1600 per annum per mile of double-track and 8% of the gross receipts, and, when the receipts exceed $1 000 000, 10% is to be paid.

In the City of Washington the amount of pavement to be cared for by the street-railway companies is provided for by an Act of Congress approved June 11, 1878, which requires that: "When any street or avenue thru which a street-railway runs shall be paved, such railway company shall bear all of the expense for that portion of the work lying between the exterior rails of the tracks of such roads and for a distance of 2 ft from the exterior to such track or tracks on each side thereof and of keeping same in repair, but the said railway company, having conformed to the grades established by the Commissioners, may use such cobblestones or Belgian blocks for paving their tracks or the spaces between their tracks as the Commissioners may direct."

European Practice. In Europe, practically the same requirements are made. However, in the larger cities the street-railways are often owned and maintained by the cities themselves; this is especially true in Glasgow and Vienna. In London the London County Council controls and operates both the surface and the underground roads.

British Requirements. General construction of railways in Great Britain is governed by the Tramways Act of 1870. As regards pavements this act provides that

the companies shall repair and maintain the space between the tracks and 18 in on each side. If the work be not properly done, it may, after 7 days' notice, be put in good condition by the road authorities and charged to the companies.

In Amsterdam, Holland, the street-car company is obliged to put the street in good order after construction and to maintain the pavement between the rails and 20 in on each side, and, where the street is not paved, the entire space must be paved by the company. In addition to this the street-car company pays the city the sum of $600 000 annually for general widening of streets, construction and paving of new roads, the building of new and changing and widening of old bridges, the filling and earthing over canals and laying sewer pipes. It may be said that the writer, in an inspection trip thru many of the principal cities of Europe in 1913, found the pavement in the railway area of Amsterdam in a generally bad condition.

The City of Berlin has entered into a very elaborate and specific contract with the street-railway companies. The requirements for laying and maintaining pavements are entered into in great detail, but, in the main, compel the companies to lay a permanent pavement, whenever the remainder of the street is so paved, in the space occupied by the tracks and to a distance of 12 in on both sides of each rail. They are required to keep the pavement between the rails and 26 in outside in good condition.

In Hamburg, Germany, a contract made between the city and the largest of the railway companies requires the company, for a period of 25 years beginning in 1894, to pay the city in lieu of any paving or street cleaning a charge of 1 pfennig (¼ cent) per passenger carried for a cash fare, and 5% on commutation tickets.

3. Location of Car Tracks

After it has once been determined to construct a street-car track in any street the next thing to be determined upon is its location. Ordinarily it is the custom to locate all tracks in the center of the street. As a general proposition this practice is undoubtedly correct, but conditions often arise where it is better to vary the location, and sometimes when the tracks are laid in the center of the street they are separated entirely from the roadway.

Tracks in Sidewalk Space.

In Rochester, N. Y., on streets in the suburbs where the roadways are narrow and the sidewalk space wide, the tracks are sometimes laid in the sidewalk space between the curb and the walk, thus leaving the roadway entirely free. This of course makes it necessary, when using vehicles, for all residents on the street to cross the track in going from their property to the roadway.

Tracks at the Side of Roadway. In some cities the tracks are located in the roadway, but next to the curb. This practice leaves the center of the roadway entirely clear, but it prevents vehicles from being left standing at the curb and makes it awkward to drive up to the curb for the purpose of receiving or discharging passengers, so that the practice as a general rule is not satisfactory.

Paris. A location corresponding somewhat to this was observed in 1913 in a street running out of the City of Paris. Here, the entire street was about 100 ft wide, with the central roadway, perhaps 40 ft wide, paved with stone; in a space about 15 ft wide between the pavement curb and the secondary curb were located the street-car tracks, one on each side; the space between the secondary curb and the building line was treated in the usual way with sidewalk, etc. This, of course, left the entire roadway space free and uninterrupted for travel. The street was a semi-residential, retail-business street, where there would probably not be much passing from the stores to the street, and, in fact, there does not seem to be as much of this in Paris as in American cities.

Central Park West, Borough of Manhattan, New York City. Sometimes, however, where a street runs alongside a park for any considerable distance, the tracks are located on the side of the roadway next to the park, the nearest rail being about 3 ft from the curb. A notable case of this kind is Central Park West, which is 100 ft wide, and runs along the west side of Central Park. The roadway is 48 ft wide, the sidewalk on the east side being 27 ft and on the west side 25 ft. The east track is located with the

rail 3 ft from the east curb, the idea being to get as wide a roadway as possible for traffic. This was very satisfactory when all the vehicles were horse-drawn, but with the increase of general traffic and the speed of the automobiles many accidents have occurred because the northerly vehicular traffic is adjacent to the southerly street-car traffic, so that all people getting off the cars going south are met by the vehicular traffic coming north. Since 1915 proceedings have been under way with a view of changing the location of the tracks from the side to the center of the street, and in order to make this as inexpensive as possible it was proposed to change the location of the east track only, placing it to the west of the present west track, and to set back the curb in front of the park 7 ft. The result of this would be a total roadway of 55 ft, divided approximately into 25 ft for the roadway west of the tracks, a space of 15 ft for the street-car tracks, and 15 ft for the roadway east of the tracks. This arrangement would provide for two lines on the east side going north and three lines on the west side going south. This would relieve the tendency of traffic to crowd up to the street-car tracks in keeping to the right, as it necessarily must do under the present arrangements. This plan has been ordered carried out by the Board of Estimate and Apportionment of the City of New York, but on account of the question of how the cost of same shall be divided between the city and the company the work has not been carried out (1918).

Prospect Park West, Brooklyn, N. Y. Another location similar to this is Prospect Park West, where the tracks are located in the same way, but as the traffic on this street is not great, it not being a thorofare as is Central Park West, no trouble on account of accidents has arisen.

Tracks in the Center of Roadway. The central location, separated from traffic by curbs, is particularly desirable to the street-car companies, especially where the blocks are long, as it not only allows the cars to run more rapidly but they are less liable to be interfered with by vehicles or pedestrians.

In Coney Island Ave., Brooklyn, N. Y., the car tracks were originally located on the west side of the roadway next to the curb. This was on account of some old property rights that the railroad company had in the street. This avenue is 100 ft wide, and had been graded and curbed for a roadway of 50 ft, leaving a sidewalk space of 25 ft on each side. When it was desired to pave the street it was seen that the location of the tracks was not satisfactory, and it was much opposed by the people owning property on the side where the track was laid next to the curb. After considerable agitation and the passage of a bill by the New York State Legislature authorizing the same, the tracks were changed to the center of the avenue, and a space 24 ft wide was given to the railroad company, separated from the traffic roadway by cement curbs, and the old curbs set back 10 ft on each side. There was much discussion by the property owners as to whether this central space should be reserved for the railroad or left in the usual way for traffic. This arrangement gave two sidewalks of 15 ft each, two roadways of 23 ft each, and a railroad area in the center of 24 ft. The blocks on this avenue are some 700 or 800 ft long, but openings were left in this central space, and paved with granite, so that traffic could cross at distances of about 400 ft.

Upper Broadway, Borough of Manhattan, New York City, is wide and has parks in the center; it also has two lines of street-car tracks. These, however, are located adjacent to these central park spaces, and this is probably the best location that could be obtained, as it gives the greatest possible width for traffic, and the traffic, naturally veering to the right as it moves, keeps from rather than towards the tracks.

Beacon St., Boston, is a good example of the location of street-car tracks in the center of the street, where the tracks are separated from the vehicular traffic and the central area is sodded.

New Orleans. The most extensive example of central location where traffic is separated from the street-car tracks is undoubtedly seen in the City of New Orleans, where nearly all of the streets are so treated. Canal St., for instance, which is a business street, 120 ft 6 in wide, is treated in this way. The central portion of the street, where the tracks are located, called there the neutral strip, is 60 ft wide. In other and residential streets, and even where only one track is located, this same method is used. In a climate like that of New Orleans, where the air is moist and

where it seems possible, and even easy, to keep this neutral strip sodded and well grassed, this is a very satisfactory treatment for residential streets, but it would not seem satisfactory for business streets, as then it is desirable to have free and uninterrupted traffic from one side to the other.

4. Rails

Loads Carried by Rails. When the actual work of construction is taken up, the first and possibly the most important thing to be considered is the type of rail to be used, and in studying this question it must be understood that it is a very different proposition from what it was in the early life of street-car companies, as the cars were then light and drawn by horses, while now they are heavy and propelled by electricity. Interurban cars are generally very heavy, some coming into the City of Pittsburgh weighing 35 tons, and others as high even as 50 tons. The new cars used by the Brooklyn Rapid Transit Co., in Brooklyn, weigh 25 tons unloaded, and if it is assumed that they will carry at times 100 passengers, averaging 150 lb each, that will make an added weight of 7½ tons, or a total weight of 32½ tons, when loaded, carried on eight wheels. It can easily be seen, therefore, that track construction for such cars must not only be properly designed, but also properly carried out, and in this the design of the rail plays an important part.

Development of Rail Types. Many changes have taken place since tracks were first laid. The first track laid was undoubtedly very crude, practically a piece of flat iron spiked to a wooden stringer, with a groove in which the flange of the wheel ran, but as traffic increased it was recognized that a more substantial rail was required, and that shown in Fig. 1 was adopted. This was spiked to a stringer, which itself rested on cross-ties, the lip on the left-hand side coming down over the edge of the stringer. The spikes and the rails, however, soon became loosened, and the joint rough and uneven, but with the small cars in use at that time, and the low rate of speed, the discomfort of the passengers was not as great as might have been expected. Fig. 2 represents a rail of the same type, but used on a curve in order to prevent the cars from becoming derailed. The practically square edge of Fig. 1 made it difficult for teams to cross, especially when the pavement was fairly good, so that eventually it became modified to the type shown in Fig. 3. This allowed trucks to pass over the rails readily, but was no better for the passengers or the cars themselves. Fig. 4 shows a modification of Fig. 1, making an actual groove for the flange of the wheel, but without modification shown in Fig. 3, allowing for the easy passage of trucks. If a block pavement had come up against the back of the rail this would not have been necessary, but in the early days pavements were not often so laid. Fig. 5 shows what was generally known as the center-bearing rail. This was practically Fig. 4 doubled. It was claimed by many that the main object of this rail was to make it as obnoxious as possible to vehicular traffic, and anyone who has seen this construction in paved streets knows how successfully it would have accomplished this purpose. The companies claimed, however, that naturally

Fig. 1

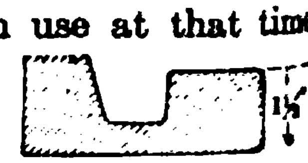

Fig. 2

Fig. 3

Fig. 4

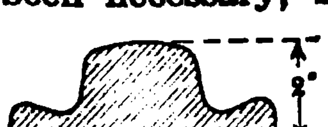

Fig. 5

the wear would be on the inner side of the rail, and that after that was worn the rail could be reversed and the wear taken on the other side. This type of rail was laid in duplicate, with both rails on one stringer, on 14th St., New York City, just west of Broadway.

Removable Heads and Reversible Rails. At one time it was thought that, as the head of the rail was the only portion that received any wear, it might be possible to so design a rail that the head could be replaced, leaving the lower portion intact. In order to accomplish this the rails were made in two parts, as shown in Fig. 6. Fig. 7 shows a type of rail designed to accomplish the same purpose, but of an entirely different type. It must be remembered that if a proposition of this kind were practicable, and a rail could be renewed without disturbing the ties or the base of the rail even, much economy would be effected. This type of rail was used to quite an extent in the street-car system of Brooklyn in 1895. However, the development of street-car transportation made it necessary to change the power from horses to electricity, and also to increase the size and weight of the cars, and it was found that it was not practicable to use rails of this type, as the support was not sufficiently rigid. Fig. 8 shows a center-bearing rail of a design that could be reversed after one side had been worn by the wheels. This style of rail would be extremely objectionable to traffic from both the inside and the outside of the rail, and it was never used to any great extent.

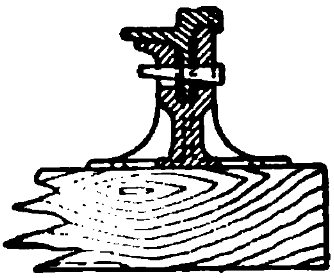

Fig. 6

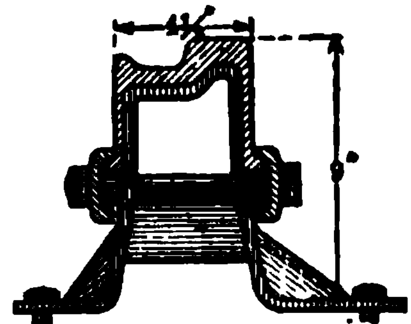

Fig. 7

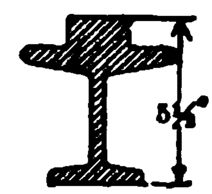

Fig. 8

Side-Bearing Rails. Fig. 9 shows what is known as the side-bearing rail, and was undoubtedly the first form used of this kind; it has not come into very general use. It is particularly attractive to vehicular traffic, especially when the pavement of the roadway is bad, as it generally was when these rails were first adopted, but, on account of its shape, it is difficult for a truck to turn out readily. Also, on account of its wide tram, it is difficult to pave up to it with any kind of a block pavement, as any little settlement at the end of the block will bring it below the tram of the rail, when abnormal wear will occur and a rut soon form. This often took place, as at the time this rail came into use concrete foundations for pavements were very rare.

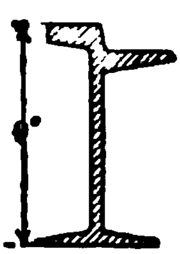

Fig. 9

Grooved Side-Bearing Rails. Fig. 10 shows a grooved side-bearing rail which for many years was the standard rail of New York City. It is known as the Trilby rail. The lip of this type extends to a considerable distance beyond the groove, also forming a convenient wheel track for any vehicle the tires of which are so wide that they will bear on the rim rather than settle in the groove. This has the same objection as that referred to in Fig. 9, of being difficult to pave up against, on account of the long distance between the edge of the lip and the gauge line. This type is objectionable also for the very reason that it invites traffic. The typical rail is one that should neither invite nor repel traffic, but allow it to pass crosswise or diagonally without any interference. Fig. 11 shows practically the same rail, but modified, first, as to the groove,

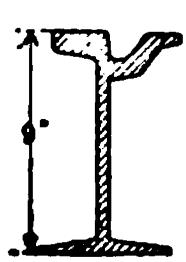

Fig. 10

which is designed so as to be as nearly self-cleaning as possible, and, second, by changing the lip, making it narrower and so reducing the space between the edge of the pavement and the rail, and the lip is at practically the same elevation as the head, so that traffic can pass freely in any direction. These center-bearing rails were designed when granite blocks having a depth of 7 or 8 in were laid. It is not an economical type, as, on account of its height, the web requires more metal than would otherwise be necessary. When granite blocks were reduced to a depth of 5 in, the type of rail was changed to that shown in Fig. 12, weighing 105 lb per yd, which has all the good features of the other rails and gives as good service to the companies, with less metal. This type was used by the Manhattan Bridge Three-Cent Line, previously referred to.

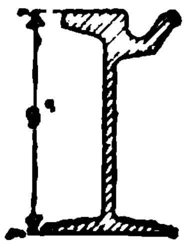

Fig. 11

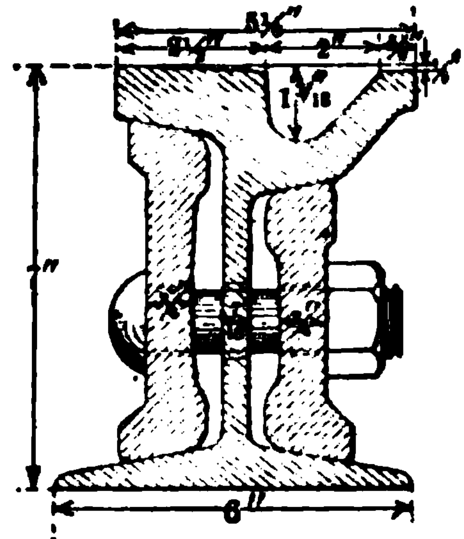

Fig. 12

Life of Rails. It is often asked, as in all other construction, how long will rails last in a street-car track. This question is as indefinite as most questions of like character, as the life of the rail depends so much upon conditions, namely, the weight of the car to be used, the speed at which it is to be operated, the size and cross-section of the rail itself, the foundation upon which the structure is placed, the method of construction, whether the rails are on tangents or curves, and whether there is much starting or stopping on the line. All these matters have a very important bearing on the question, as can easily be understood, and without knowing these conditions it is impossible to form any estimate whatever as to the life of the rail. Some engineers, working by the rule of thumb method, have estimated that a rail will last for the passage of 6 000 000 cars. The above discussion shows how general an estimate this must be. In the Borough of Brooklyn, New York City, on Fulton St, below the Borough Hall, rails were renewed in 1899 that were laid in 1895. This would mean the passage of a little over 2 500 000 cars over the track before it was renewed. It has been stated that the passage of the same number of cars over the Third Ave. Railroad tracks in New York City appreciably wore and hollowed out the rails. This was a cable road. At the present time in Brooklyn it is estimated that the present construction on Fulton St, which has the heaviest traffic, will last for 12 years, while some track is in existence which has been down 18 years and is still in good condition. An extreme case of wear of rails is undoubtedly shown in the operation of the New York subway. On the City Hall loop, rails wore to such an extent that some of them had to be renewed in 5 months; others had a life of from 7 to 8 months. This was on a curve with a radius of 147 ft. At the Grand Central Station, rails were removed after having been in use 12 months and 5 days. These of course are extreme cases, but indicate very plainly the necessity of having all conditions known before any opinion can be formed as to the length of time any track will be used.

5. Construction of Car Tracks

Joints. When the work of actual construction proceeds after the type of rail has been determined upon, one of the most important things to be considered is the joint making. It is recognized by all engineers that the

joint is necessarily the weakest part of the rail unless reinforced with great care. From the pavement standpoint, too, the joint question is important, as, especially when a sheet-asphalt pavement is laid up against the rail, the wear next to the track almost invariably begins at the joints. This causes the rails to work loose, and, with the motion under traffic, allows water to get below the pavement, softening it and causing undue wear. Joint trouble has been eliminated to a great extent by the construction of longer rails. The old practice was to lay rails 30 ft in length, but within recent times rails have been laid 60 ft in length, thus reducing the joints one-half. Many experiments have been made in joint making and many devices used for that purpose. This is important from a railroad traction standpoint, as is shown by a paper by Bowen (14). He stated that when the question of renewing the State St. track, in Chicago came up, a car weighing over 4 tons was run over it, attached to a grip car by means of a dynamometer. The same car was run over a track newly laid and at the same speed as over the old line. The dynamometer showed that it took 13.75 lb more pull per ton to haul the car over the old line than over the new. That he attributed a great deal of this extra power required to the condition of the track at the joints can be seen from his conclusion that a new track with cast joints would last 12 years, and as there will be no low joints, the draw-bar pull will not increase much until the rail is worn down sufficiently to allow the wheel to run on the flange. When it is remembered that some engineers figure that the force required to haul a ton on a well-constructed track should not exceed 8 lb, the effect of the track being in bad condition can be plainly understood. This is especially important as the weight of the car and the speed at which it is run increases. The original method of making joints was by fastening the rails together with steel plates and bolts, but in order to make rigid joints they have been formed by welding with what is known as the cast-welding process. More recently the practice of welding rails electrically has been in use. As the rails are used for the return current of electricity it is important that the connections should be as nearly perfect as possible. Fig. 13 shows, both in section and elevation, a riveted joint. Fig. 14 shows a continuous joint, and Fig. 15 a cast-welded joint, all as used by the Brooklyn Rapid Transit Co.

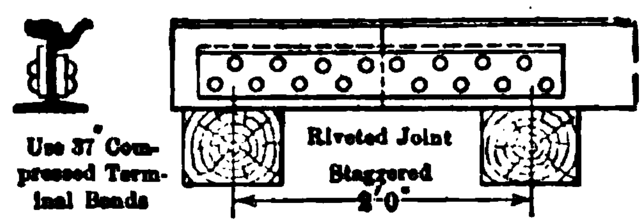

Fig. 13

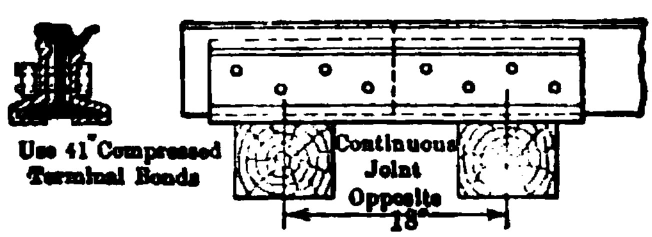

Fig. 14

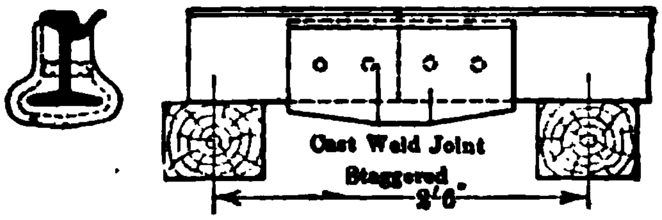

Fig. 15

Ties. It is generally considered good practice, where wooden ties are used, to have them creosoted before being laid, as, with a permanent track construction, if the ties need not be disturbed when the rails are laid, the cost of relaying the track is much reduced. Some companies use steel ties, as will be shown in the different types of paving construction listed, but many like the wood bearing because it gives more resiliency to the rail.

Third Ave. Railway Co., New York City. Fig. 16 shows the form of construction that was adopted when the company substituted electric construction for cables,

about 1899. It will be noticed that the rail is the regular Trilby rail, set on a wooden creosoted stringer. The object of the stringer is to get a certain amount of resiliency in the track so as to make it more comfortable for passengers and easier on the cars themselves. Yokes were placed 5 ft apart from center to center. This construction was used on the subsidiary lines, but on Third Ave. proper the form of the yoke was somewhat changed, and instead of the creosoted beam a heavy spring was used, resting upon the yoke and upon which the rail rested. This spring is so designed that, when the center is depressed, the ends rise, presenting a corrugated surface of such strength that it is assumed it will sustain a weight of 10 000 to 12 000 lb. The springs are 4 in wide, and the deflection at the passage of a loaded car carrying about 6 400 lb on each wheel is about 1/32 in and is noticeable from the street. At the time these tracks were laid the pavement outside of the tracks was granite block, but, as will be seen from the construction of the yoke, it would be extremely difficult to lay a satisfactory granite-block pavement between the rails and the center slot, so concrete was laid to within 2 in of the top of the rail, when about 1 in of asphalt wearing material was spread over the concrete, in which was imbedded a specially designed grillwork of $^3/_4$-in cast-iron bars, forming squares about $3\frac{1}{2}$ in in size. More asphalt was then filled in on top of that first laid, between and around the iron bars, and thoroly rolled and compacted so that the finished surface was in a straight line between the slot and the head of the rail. This form of pavement did not prove to be very satisfactory.

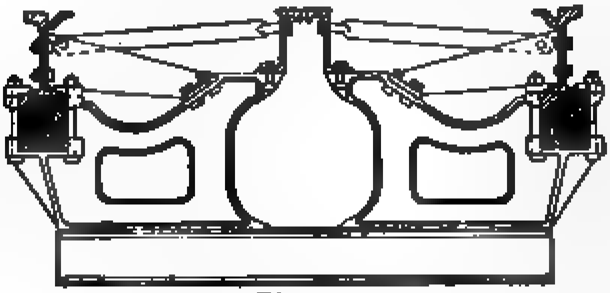

Fig. 16

New York Railways Co. work in the Borough of Manhattan, New York City, in 1915, is shown in cross-section in Fig. 17. It will be noticed that the construction is practically the same as that of the Third Ave. Line, except that the rail rests directly on the yoke and not on the wooden stringer. The yokes are placed 5 ft apart and serve as bearings for the rails.

Coney Island Ave., Brooklyn, N. Y. In the construction on Coney Island Ave., the roadbed was excavated to a sufficient depth, and then broken stone spread over the surface and rolled to a depth of 6 in. Upon this bed of broken stone creosoted ties were placed and T-rails laid upon them. The rails were fastened to the ties with a screw spike pneumatically driven. A T-rail was permitted to be used as the track was nearly all laid in a space separated from traffic, while at the intersections vehicular traffic would be nearly at right angles to the track. This method has been entirely satisfactory.

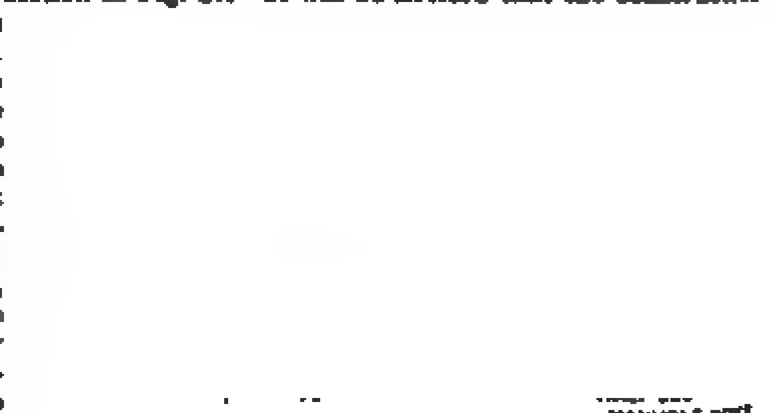

Fig. 17

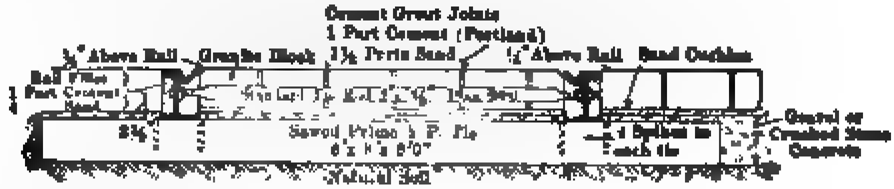

Fig. 18

Brooklyn Rapid Transit Co. Fig. 18 shows the type of track construction in Brooklyn as adopted by the Brooklyn Rapid Transit Co. It will be noticed that the ties are laid upon the natural soil. In this connection it should be said that the soil of Brooklyn is sandy and artificial drainage is not necessary. This company has laid a good many miles of track of this character, with extremely satisfactory results. As a general proposition, however, it would seem that some kind of artificial foundation was necessary, but this must be determined by conditions. Fig. 19 shows a type of construction with steel ties of the Brooklyn Rapid Transit Co. A track laid in this way was constructed on Flatbush Ave., leading out towards Prospect Park, and has proved exceedingly satisfactory. Vehicular traffic can pass over it freely from one side to the other, either diagonally or directly across, without any interference whatever. It is exceedingly pleasing also to ride over, as the rails along the foundation are solid and the track surface correspondingly smooth.

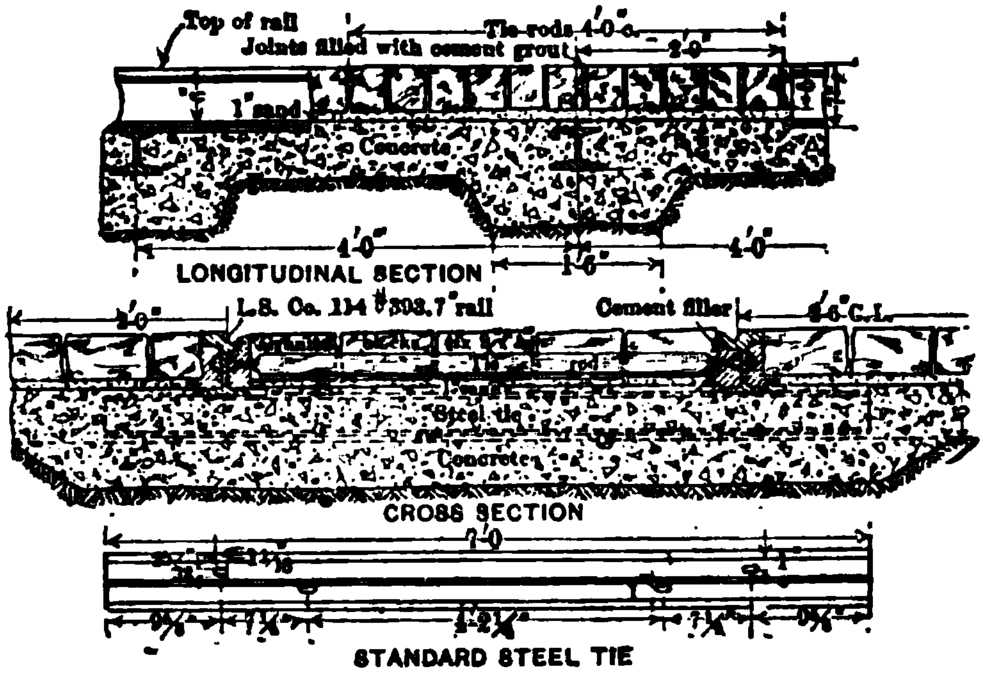

Fig. 19

Cleveland, Ohio. Fig. 20 shows a somewhat similar construction used in Cleveland. The joint fastening should be noted, as the plates extend the full depth of the web.

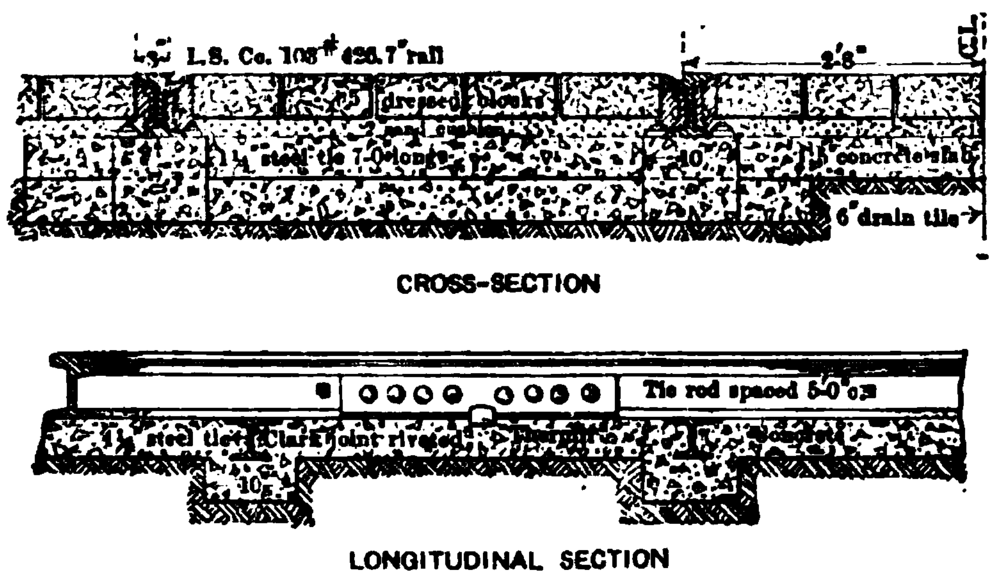

Fig. 20

Rochester, N. Y. Fig. 21 represents a cross-section of a portion of a car track in Rochester as used in 1900. It shows plainly the concrete beam under the rail and the steel tie which was used at that time. Fig. 22 shows another portion of the same construction. The

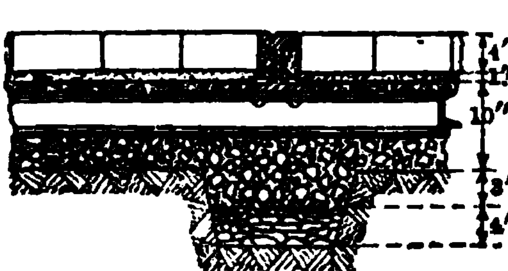

Fig. 21

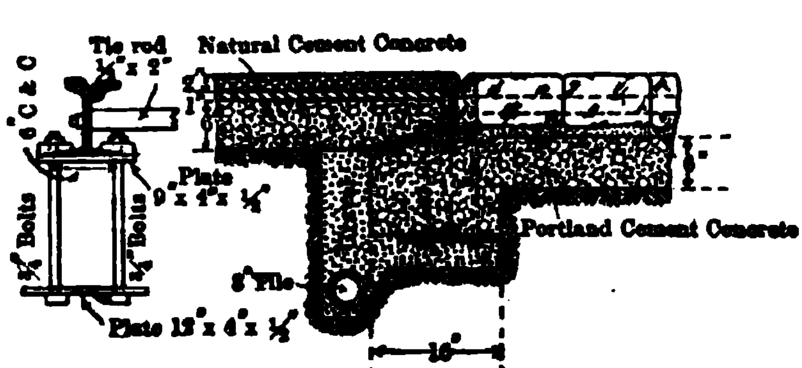

Fig. 22

rails were clamped to the concrete beam, as shown, there being three clamps to a 30-ft rail and five to one 60 ft in length. A cushion of asphalt mastic ½ in thick was laid

on top of the concrete beam, making the same more resilient. Attention is called to the provision for drainage should any water seep thru the joints of the blocks down to the sand cushion. The soil of Rochester is clayey, so that provision for drainage is necessary. Fig. 23 shows a cross-section of street-car track construction in Rochester in 1915. The Consulting Engineer of that city writes, as follows: "We are satisfied, from our experience, that a broken stone foundation is better for heavy traffic, especially where it is difficult to keep the street closed for a sufficient length of time to let the concrete become properly set. We have tried every kind of construction in railway tracks and are satisfied that the T-rail with a special Medina or granite block, cut as shown on the print, makes as good a track as any other construction, and very much better than any of the other half-grooved rails that have been used heretofore. We have abandoned the use of the steel tie and are using wooden ties entirely at the present time. These ties are spaced 2 ft apart."

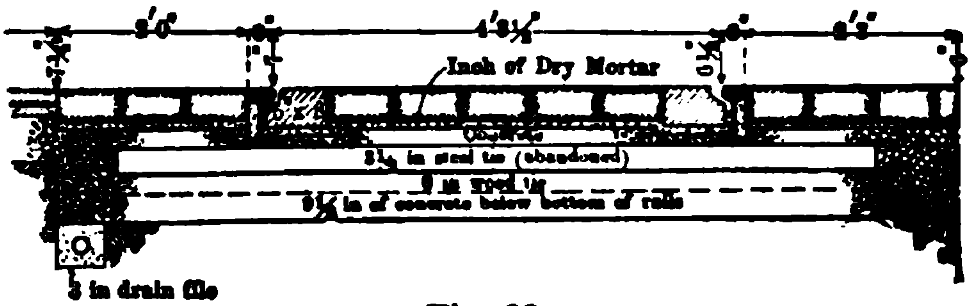

Fig. 23

Detroit. Fig. 24 shows the standard track construction in Detroit in 1912, a T-rail being used. It will be noticed that the ties are bedded in concrete and that the joints are cast-welded. Fig. 25 shows a grooved rail construction in the same city in 1913.

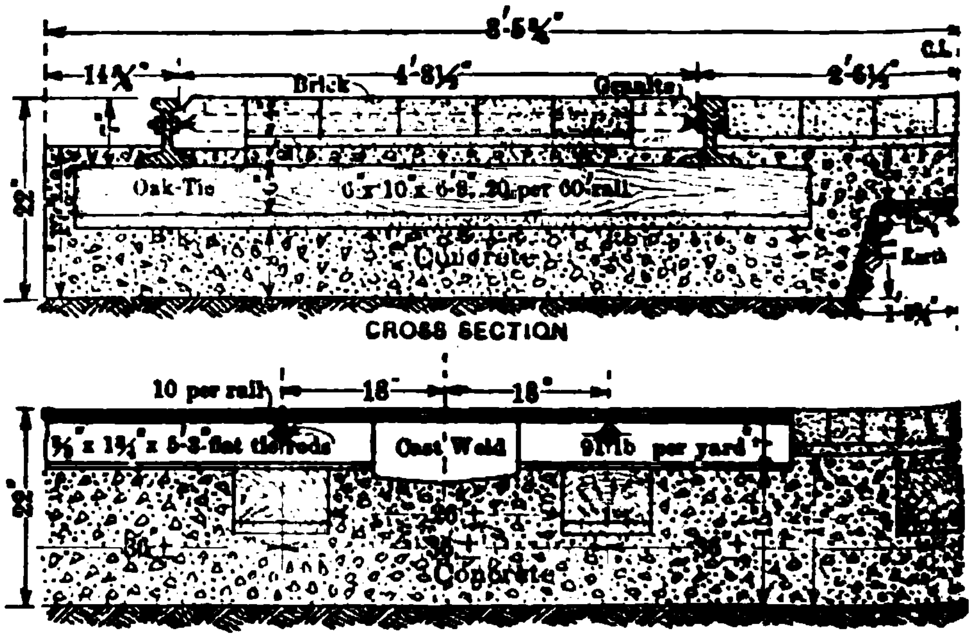

Fig. 24

Kansas City, Mo. Fig. 26 shows construction in Kansas City as of 1912. Attention is particularly called to the type of rail and the result obtained when a block pavement is laid up against it. It is extremely objectionable, as was undoubtedly ascertained by the company, as Fig. 27 shows standard construction in the same city as of 1913, the rail being of the T type.

Newark, N. J. Fig. 28 shows standard construction in Newark in 1912, and Fig. 29 construction in the same city for 1913. The construction is practically the same, altho the pavement is of a different character.

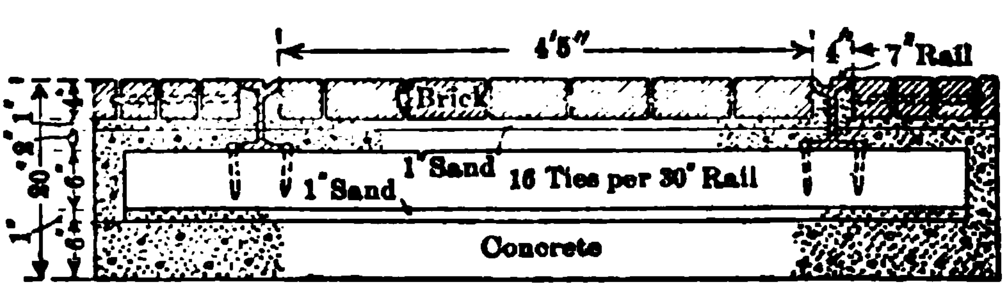

Fig. 25

Philadelphia. Fig. 30 shows track construction in Philadelphia. This, as will be seen, varies materially from construction in other cities, the rails being placed on chairs embedded in the concrete. Attention is called to the way the outside edge of the rail is bevelled off and how unnecessary this is when a square block is laid against the rail. In 1915 it was stated that the concrete construction had practically been abandoned and the ties laid on the natural ground.

Boston. Fig. 31 shows Boston construction in 1912, the grooved rail being set upon

ties in much the same way as was shown in Cleveland and Brooklyn. Fig. 32 shows construction in Boston in 1915. The Engineer of the road states, in connection with this, that the tendency now is to do away with concrete in foundation for tracks, on account of its being too rigid, and broken stone is generally used in its place.

The Board of Supervising Engineers of Chicago adopted the different types of construction shown in Figs. 33 and 34, the method varying according to the rail and foundation.

Fig. 26

Toronto, Canada. Fig. 35 shows track construction as used in 1915 in Toronto. The Commissioner of Works of that city states: "During 1913 and 1914 the concrete substructure of all new track allowances in the city were 15 in in depth, being placed in two courses, the first course of 9 in being brought up level with the bottom of the tie, and the second course of 6 in being placed later. This practice is carried out in order that a firm basis may be provided for the tie and provision made for shrinkage in the concrete. We introduced, last year, wooden filler strips to take the place of the mortar casing which was formerly used, and which was always a source of trouble, and, from indications to date, we are led to believe that this form of construction will be much more satisfactory than the former."

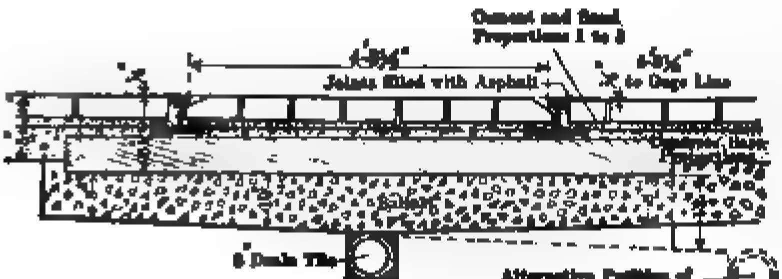

Fig. 27

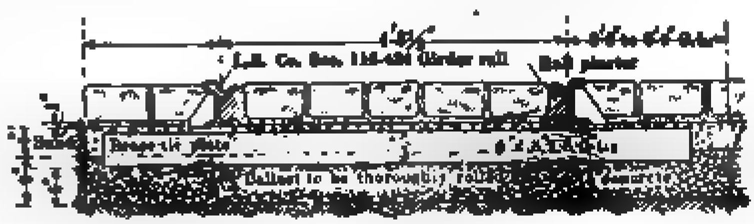

Fig. 28

Filling for Rails. It is important, especially where the pavement is made of blocks of any kind, that the space between the web and the lip of the rail be filled substantially with some solid material, as,

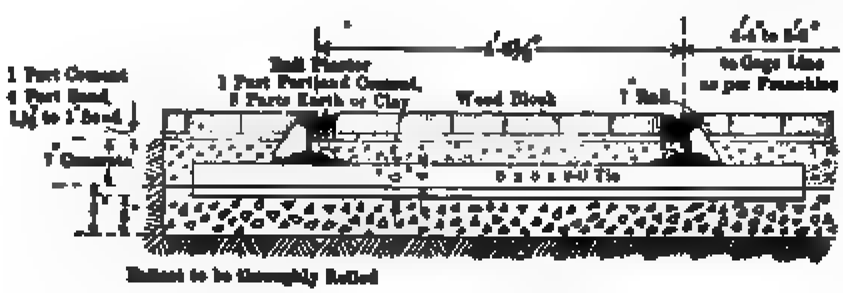

Fig 29

if it is not so filled, the blocks are liable to settle under traffic and permit a rut to be formed adjacent to the rail. Three materials are used for this purpose: Cement mortar, burned clay blocks, and wood. The cement

mortar mixed in the proportion of one part of cement to two or three parts of sand is most generally used, and is probably the best. It can be easily applied and, after it has set it is strong and solid. Burned clay brick does not fill the space exactly, and, in any event, has to be burned specially for the rail. The wood is undesirable for the same reason, and, unless creosoted, is liable to decay long before the pavement or the rail itself is worn out and thus lose the efficiency it had in the beginning.

Fig. 30

B.R. Sec. # 4 (Penn. Sec. # 279)

Fig. 31

Pavement Next to Rails. In the laying of pavement in a street-car street it is claimed by many that sheet-asphalt should not be laid

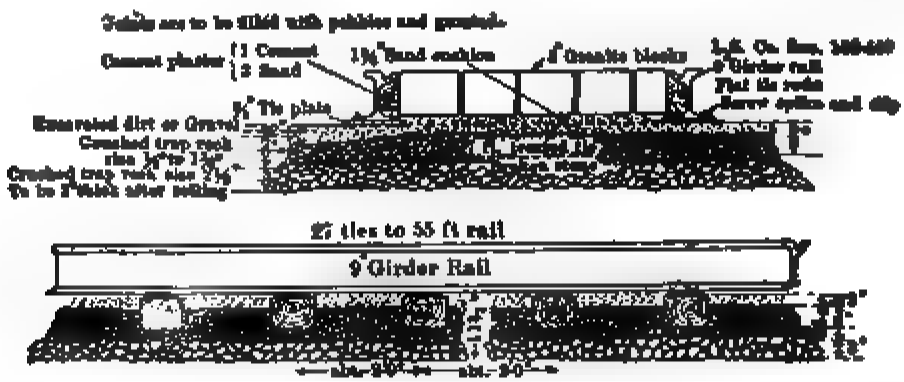

Fig. 32

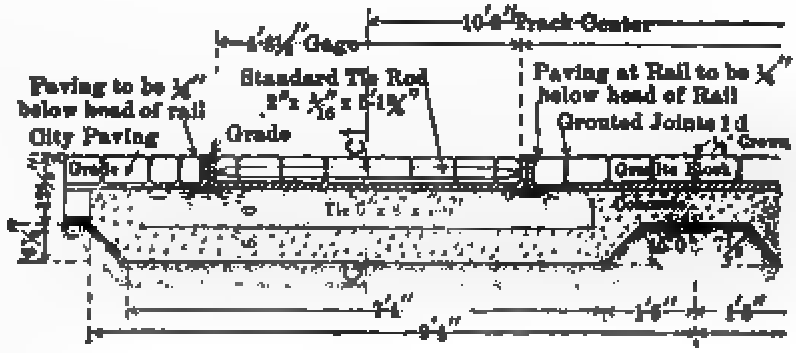
directly against the rails, as the wear will be such that it will be neither economical nor desirable. The alternative is for the street-car company to lay outside of the rail a block pavement of some kind: stone, wood or brick. While this practice has proved satisfactory in many cities, it has one objection, that is, it forms a longitudinal joint between a hard and a comparatively soft material, which is in the

Fig. 33

line of traffic, and for that reason liable to form a rut under heavy traffic. In Brooklyn, N. Y., the practice has always been to lay the sheet-asphalt directly against the rail, and very many miles of this construction are now in use. While with bad track construction it is undoubtedly true that more than ordinary wear will take place next the rail, yet with such tracks as should be laid in modern times, with the present weight of cars, it seems that the sheet-asphalt can be satisfactorily laid up to the rail itself



Conclusions, Spec. Com. Mat. Road Cons., Am. Soc. C. E. (10). "Uniformity in the roadway surface being essential for minimum wear and expense of maintenance, anything, such as manhole covers or street-car tracks, introducing an element of non-uniformity into the surface, should be counteracted as far as possible whenever surfaces of different degrees of hardness adjoin in a pavement. The traffic coming from the harder to the softer surface naturally causes abnormal wear on the latter. In the case of car tracks in streets, modern construction is such that the tracks are nearly rigid, altho this condition does not exist in all cities at present. Where it does exist, however, the pavement should be laid somewhat above the level of the rail. The Committee, however, does not believe that in any case a bituminous pavement should be laid between the tracks or between the rails of the tracks. When car tracks are laid in roads, the construction is not generally as nearly rigid as in streets, and the rails are usually of the T form. The tracks in such cases are often laid at the side of the road, rather than in the center, as is customary in streets. In the case of macadam or bituminous roadways, and when the rails are in the center, it would be advisable to lay stone blocks or brick for a width of at least 18 in

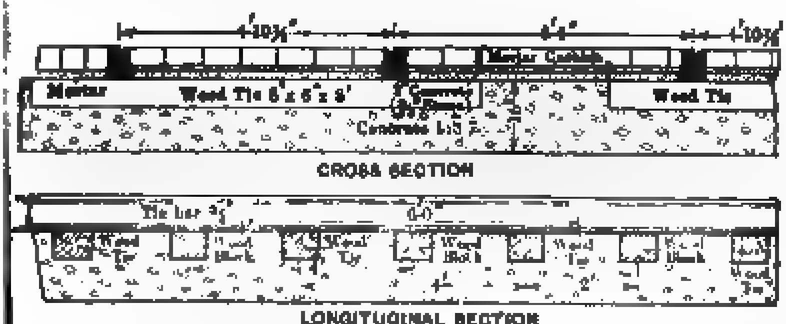


Fig. 35

Fig. 36. Cleveland

Fig. 37. San Francisco

adjacent to the rails; when the rails are at the side and the railroad area does not form a part of the roadway proper, loose broken stone or gravel may be substituted for the stone blocks or brick."

American Practice. Figs. 36 to 47 show types of different kinds of track construction in different cities of America see (22b). It will be noticed that the greater number of the rails are of the T-type, and that the groove is formed in different ways, sometimes by cutting the blocks themselves, and at other times by laying the blocks under the head of the rail, crowning them to the center. While this practice might be satisfactory from the railroads' standpoint, it does not seem that it should be accepted by the city authorities, as it conflicts so entirely with the principle that the street-car track should be part of the pavement and neither invite nor repel traffic. A pavement would not be permitted on a street with a rut in it 1 or 1½ in deep, even if the edges were bevelled off. By laying a double line of T-rails in a street there are formed practically four ruts, into which traffic will naturally go and to cross which must prove a good deal of inconvenience to vehicular traffic.

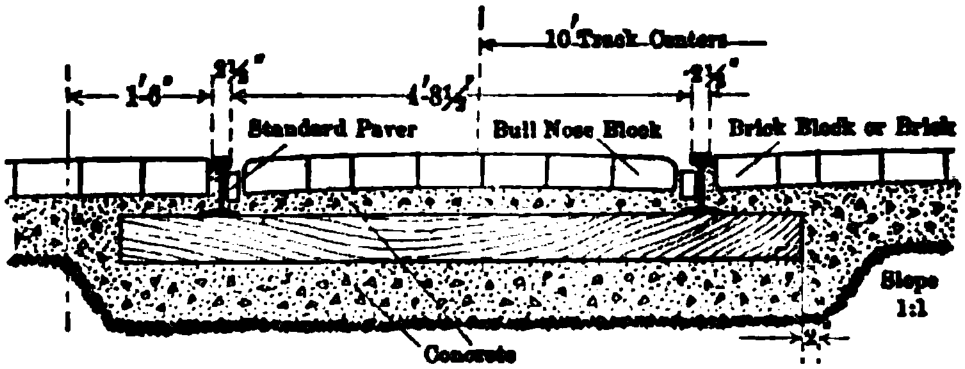

Fig. 38. Seattle

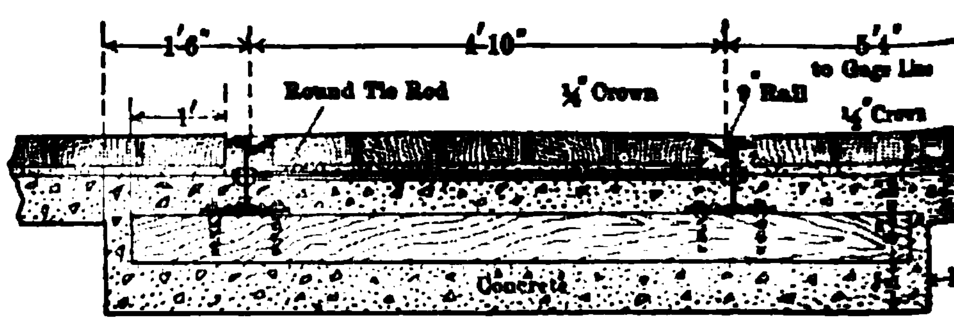

Fig. 39. St. Louis

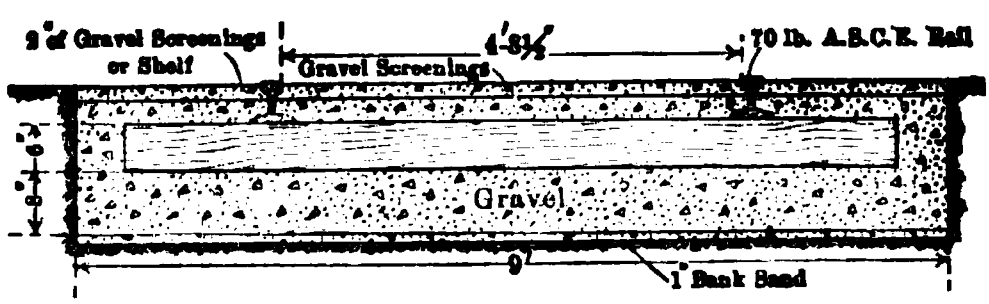

Fig. 40. Houston, Tex.

European Practice in street-car track construction is much like that of the United States, altho as a whole probably not as good. In most places the cars are small and do not require as solid construction. In the larger cities, however, where the double-deck cars are in use, it is essential that the tracks be laid with a great deal of care.

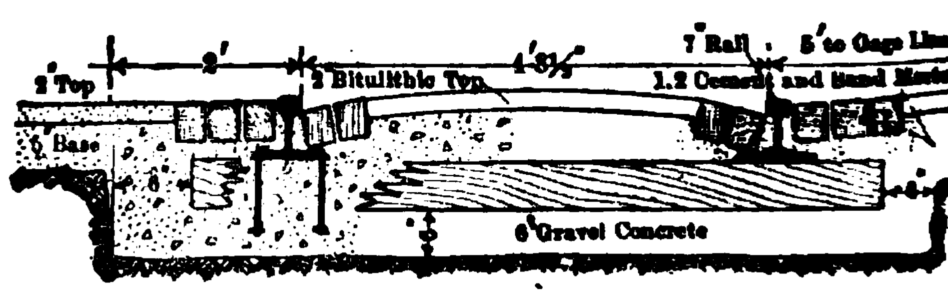

Fig. 41. T-Rail Construction, Dallas, Tex.

La Haye and Geneva, Switzerland, construction is shown by Fig. 48. It will be seen that at La Haye, where the street itself is paved with rock asphalt, wood blocks are laid up against the rail, both on the inside and the outside; also that, while the rail is set on concrete, it is bedded in asphalt in order to get more resiliency. I

Geneva it will be noticed that the rail rests on a chair, which in turn is fastened to a steel tie. Fig. 49 shows the method of laying the rail on a hollow concrete stringer at Geneva. It will be noticed that there is a small base resting upon the concrete stringer.

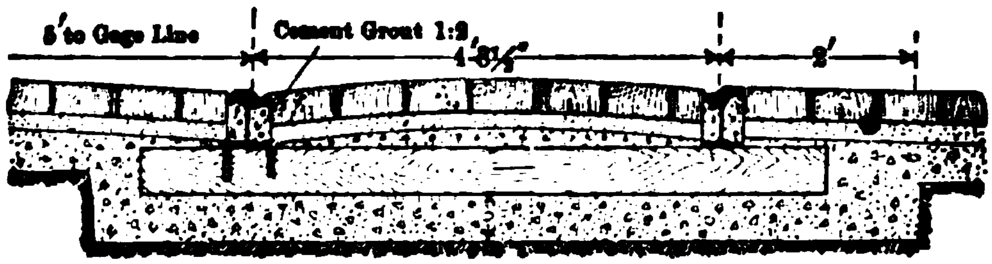

Fig. 42. Girder Rail Construction, Dallas, Tex.

Germany. Fig. 50 shows different examples of steel car-track construction in Germany: A, representing non-rigid construction in Düsseldorf and Berlin; B, semi-rigid construction at Neuchâtel; C, rigid construction at Neuchâtel; D, construction with reinforced concrete blocks at Elberfeld and Brunswick. Fig. 51 is an example of track construction with reinforced concrete in Berlin. It will be noticed from the shape of the rail that it is extremely shallow. Fig. 52 shows a cross-section of track in Berlin with a regular standard rail, the pavement being asphalt. Attention is called to the method of bringing the rail to exact grade by the wedges under the rail itself. Fig. 53 shows a longitudinal section representing clearly the method of attaching the rail to the steel cross-tie, and showing the concrete bearing for the tie itself. Fig. 54 shows track construction with monolithic reinforced concrete at Nuremburg.

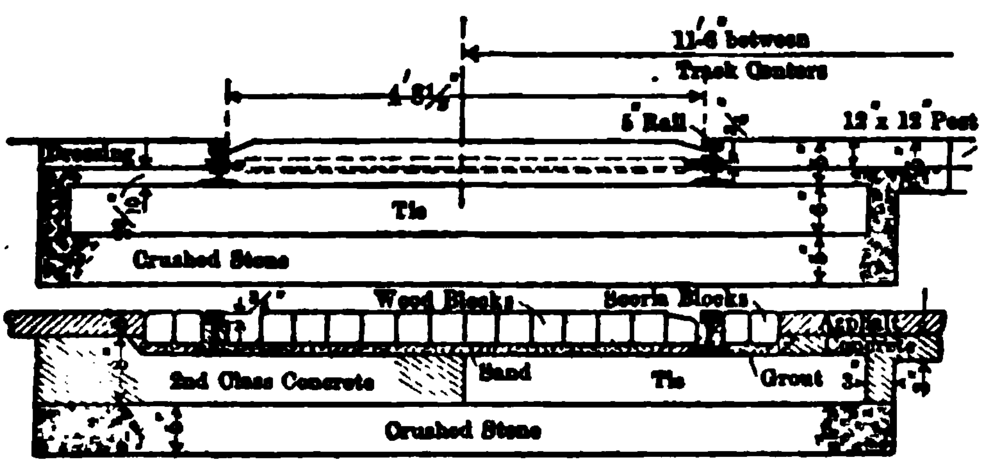

Fig. 43. Capitol Traction Co., Washington, D. C.

Vienna. Fig. 55 shows a cross-section of overhead track construction in Vienna. The rails are set directly in the concrete, and in this particular instance, altho the pavement is rock asphalt, a wood block is set next to the rail. This construction shows the rails laid in concrete, altho sometimes they are set on broken stone. It will be noticed that the rails are tied together by a wide steel bar. Fig. 56 shows underground construction, the slot rail being at the side and serving as a bearing rail for wheels as well as for the slot. The street-railway system of Vienna is owned and operated by the city, and the engineer in charge informed the writer in 1913 that, while he appreciated that the side-slot construction was better for the pavement and for the street, it was not as satisfactory from an operating standpoint. This is probably because it is more difficult to transmit the current thru the side of the car to the underground conduit than thru the center. Side-slot construction was seen in Brussels as well as in Vienna.

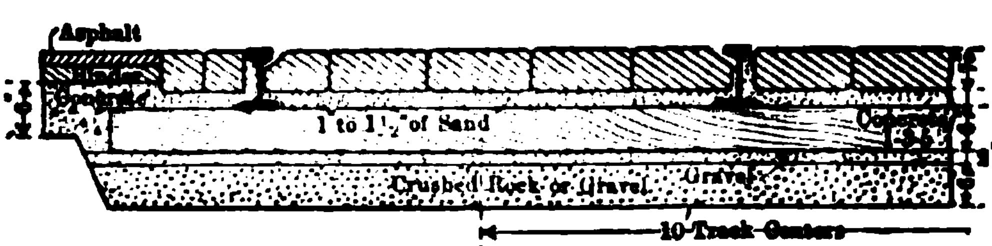

Fig. 44. Minneapolis

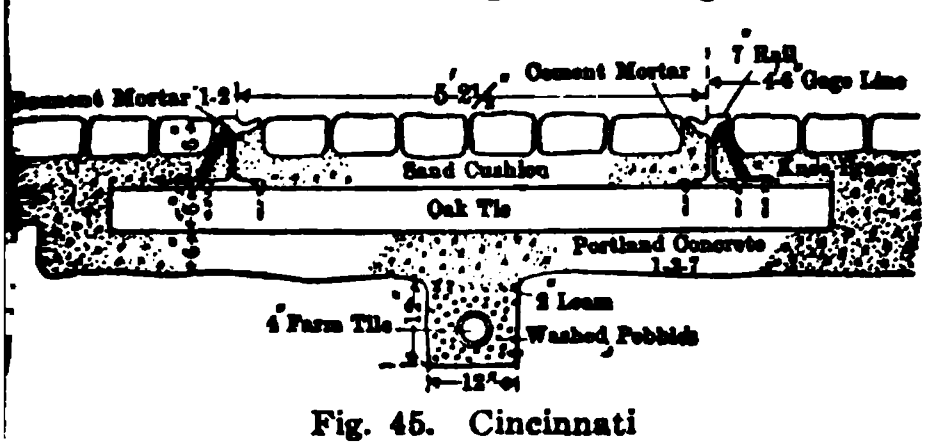

Fig. 45. Cincinnati

Paris. Fig. 57 shows two types of construction in Paris. It might be said in this connection that in 1913 the street-car system of Paris was undergoing many changes. At that time the cars were operated by the overhead and underground electric systems, and also by steam surface cars. The tracks and the pavement between the tracks in many cases were in bad condition. This was said to be because the system was undergoing a change, and it was expected that in 1915 all the lines would be operated by electricity.

Bordeaux, France. Fig. 58 shows a girder rail in concrete in Bordeaux. Here, the rail rests directly upon the concrete, and the rock asphalt pavement is separated from the rail by specially prepared asphalt mastic.

Fig. 46. Buffalo

London County Council. As has been said before, the tramways in London are controlled and operated by the London County Council. They operate both below and above ground, by overhead and underground trolleys. Fig. 59 shows a cross-section of the construction for the overhead trolley. This shows the welded rail joint. Fig. 60 shows this joint in elevation, as well as the methods of reinforcing the rails by what are termed intermediate anchors near the joint. It will also be noticed that there is an extra connection between the rails so as to permit free transmission of the electric current. The engineers evidently recognise that the joint is the weak part of the rail, and provide for extra support as shown. Fig. 61 shows a cross-section of the track for underground construction

by what is known as the extended yoke, showing the bearing of the rail upon the yoke itself. Fig. 62 shows a cross-section at a short yoke. Fig. 63 shows a cross-section between the yokes. The extended yokes are spaced 7 ft 6 in center to center and the short yoke is midway between them. Fig. 61 shows a method of making the joint, which varies somewhat from the joint in the track with overhead construction.

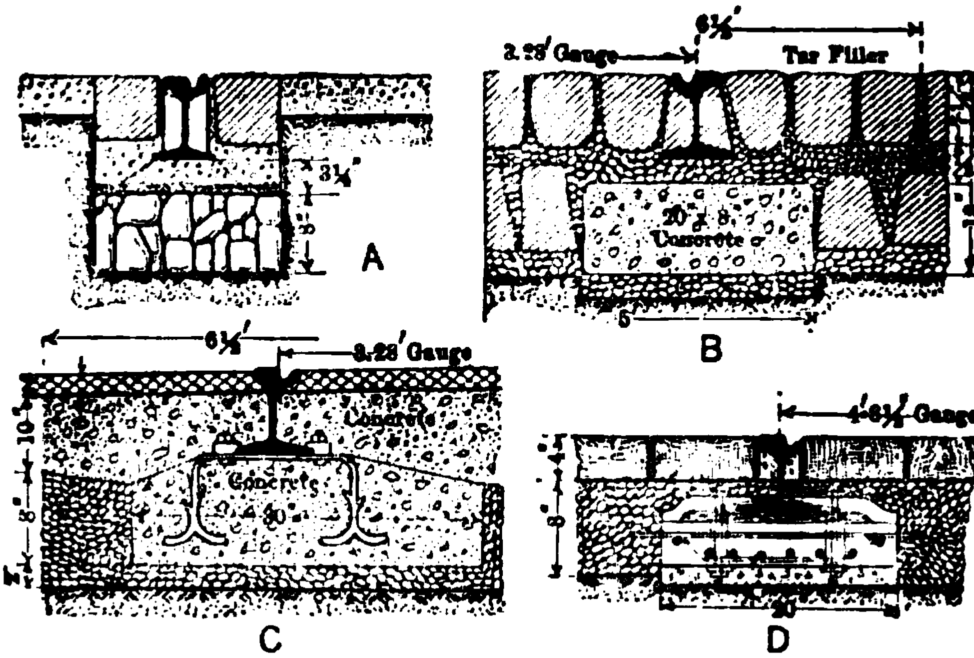

Fig. 50

Construction from Railroad Companies' Standpoint. What has been said before refers to track construction from the city's standpoint. It is interesting as well as instructive to take up the matter from the railroad companies' standpoint, and the question has probably never been better presented than in the 1914 Rep., Com. on Way Matters, Am. Electric Ry. Eng. Assn. (9b). As an introductory to the report, it is stated:

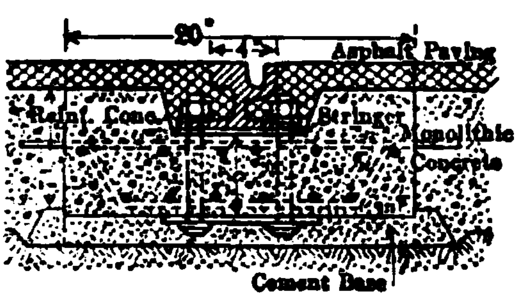

Fig. 51

"The first requirement of all types of structures is permanency. This is particularly true in relation to electric railway tracks in paved streets, where as a rule the types of pavement found are costly and both the railway and the street traffic are heavy, necessitating high expense for all structures occupying such streets when repairs are required. Such repairs then must be kept to a minimum and track structures should be designed with that end in view. However,

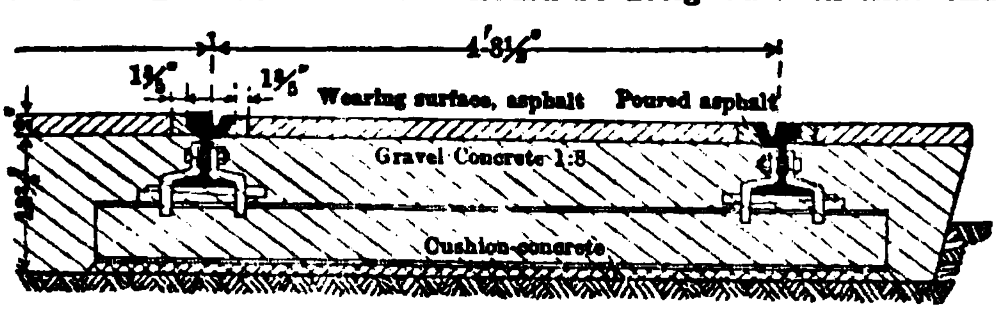

Fig. 52

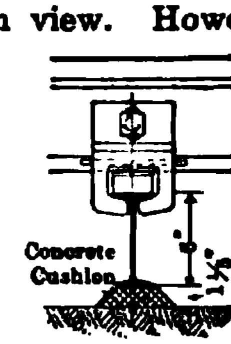

Fig. 53

permanence as applied to railway structures is a relative term and should be understood to mean a state of long durability rather than one of final and absolute fixedness for all time. The permanency of such structures therefore may be considered as meeting the varied requirements if the state of durability is well maintained at the lowest cost per year at the end of a predetermined period of permanency."

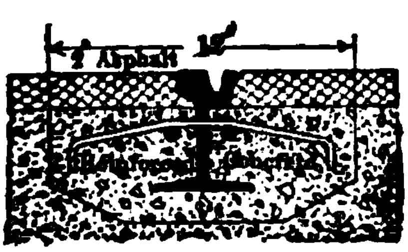

Fig. 54

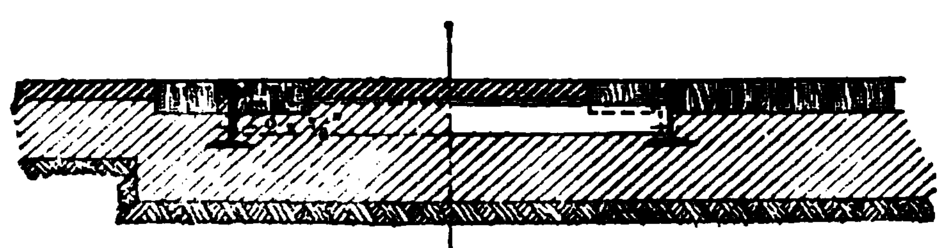

Fig. 55

The Board of Supervising Engineers of the Chicago Traction, in 1909, stated that 20 years was the assumption for the estimated life of track substructure because of the lack of definite information as to life. It was also assumed that the renewal of substructure at the time of renewal of rails would be necessary. The object of the Board was to produce as nearly as possible a permanent structure. The report continues: "As a result of this the board first adopted a solid concrete steel-tie construction without sub-drainage, but quite soon a modification was made by the substitution of wood ties with a closer spacing. After a further experience and partly to provide for unfinished street and subsurface conditions, a stone-ballasted construction, with subsoil drains where necessary, was evolved, and it is now understood that this last type of construction is being used to the complete exclusion of the earlier types. It appears, then, that design may be directed with the view to providing a structure which will be permanent only to the extent of giving durable service with a minimum of maintenance for a period of from 20 to 25 years. It is not only reasonable but also consistent with experience to expect some maintenance expense due to the numerous uncontrollable factors, and the design should be centered upon the lessening of first cost as much as is warranted by the use of first-class materials and workmanship with a type of construction which requires the least amount of expense for repairs."

Fig. 56

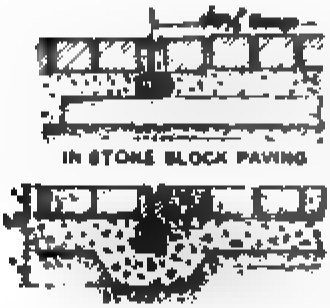

Fig. 57

Fig. 58

Weight of Cars and the Loads and Wear to the Track Construction. The report says: "From statistics in hand it is found that the modern types of prepayment cars, which are coming more and more into use, vary in total weight, fully equipped, from 32 246 to 54 700 lb, and seat an average of 45 people per car, giving an additional weight of 6525 lb if 145 lb per person is taken as average weight. If standing room is considered for an average of 40 people, or a weight of 5800 lb more, the total average heaviest passenger-load per car can be taken at 12 325 lb. Adding this to the minimum and maximum car weights gives a range of load from 44 571 to 67 025 lb."

Fig. 59

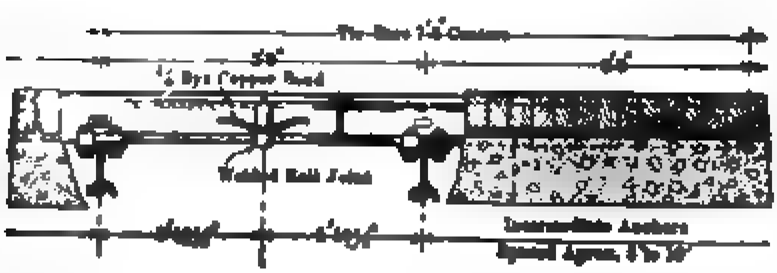

Fig. 60

Ballast. With reference to the ballast used in the substructure, it is stated that only 20% of the roads reporting used concrete ballast, altho it was admitted that the statement might be somewhat misleading, as it was made out on a road rather than a mileage basis.

The ballasted construction was preferred by 60%, solid concrete by 33%, and concrete sub-ballast by 7% of the companies reporting. The report further says:

"The preference for CRUSHED STONE or GRAVEL ballast is stated to be for the following reasons: Lower cost; ease of installation under traffic; provides better drainage; cheaper and easier to repair; concrete too rigid; experience proved it very satisfactory; gives more resiliency to track; good repairs more practicable, concrete too expensive and not generally necessary; makes less noisy track.

"CONCRETE is stated to be preferable for the following reasons: Less liable to give trouble on account of settlements; because we have no cutting under our roadbed; when grade is fixed and all substructures are in place concrete is preferred; for its supporting qualities over excavations; lower maintenance cost; with clay soils."

Fig. 61

It is interesting to note that the report states that neither headway nor speed has much influence on foundation excepting that where joints are poor or corrugation is present in rails the speed undoubtedly adds to the damage resulting from such conditions. And, referring again to the report of the Supervising Engineers of the Chicago Traction, it quotes. "Only the actual weight of the car seemed to affect deflection, and no wave motion in rail existed, for no deflection could be discovered except when the car was actually over the point of reading."

Fig. 62

Fig. 63

Fig. 64

Ties. The report states that the prevailing practice on electric roads calls for 6-in by 8-in by 8-ft ties on 2-ft centers, and that this size and space is considered the best practice. It further states that the proper spacing of steel ties is equally important; that a spacing of 4 ft has been customary, but that it has been found by experiment in Chicago that 3 ft would be more desirable, but that at this point the cost becomes excessive and leads to the use of wood.

Rails. "Deep types of rails are a necessity for work in paved streets and those under 6-in in depth will not satisfactorily provide for most types of permanent pavement. A minimum depth of 7 in is now most preferred, and it is rapidly becoming standard, as is shown by its recent adoption in Boston. Either girder-grooved or T-rails may be used with equally good results, provided a good joint is used. The points in favor of the T-RAIL may be given first, and the chief ones are as follows: (1) The T-

rail is generally considered to be designed on better mechanical lines. (2) More satisfactory mechanical joints can be manufactured, partly because of the symmetry of the rail outline. (3) The flangeway is more suitable for variable wheel flanges. (4) The rails have a longer life as a rule, under equal traffic, with a lessening of street openings for renewals. In theory the life of the ordinary joints is probably longer with a lesser amount of disturbance of pavement at the joint. (5) Many installations of T-rails in paved streets in recent years have satisfactorily met the local conditions. Several cities have required the adoption of high T-rails in replacement of tram and girder-grooved rails. (6) Much objection has been improperly directed against T-rails when it should have been brought against the pavement. This has been proved by the installation of modern pavements with old high T-rails. The points against the T-rails are as follows: (1) It is more expensive per foot of finished track and pavement. (2) Lack of self-cleaning flangeway. (3) Increased wear of pavement adjacent to rails, under extreme traffic conditions, resulting in high paving maintenance. (4) Apt to offer somewhat greater resistance to vehicular traffic. (5) Difficulty in preventing seepage of water in flangeway."

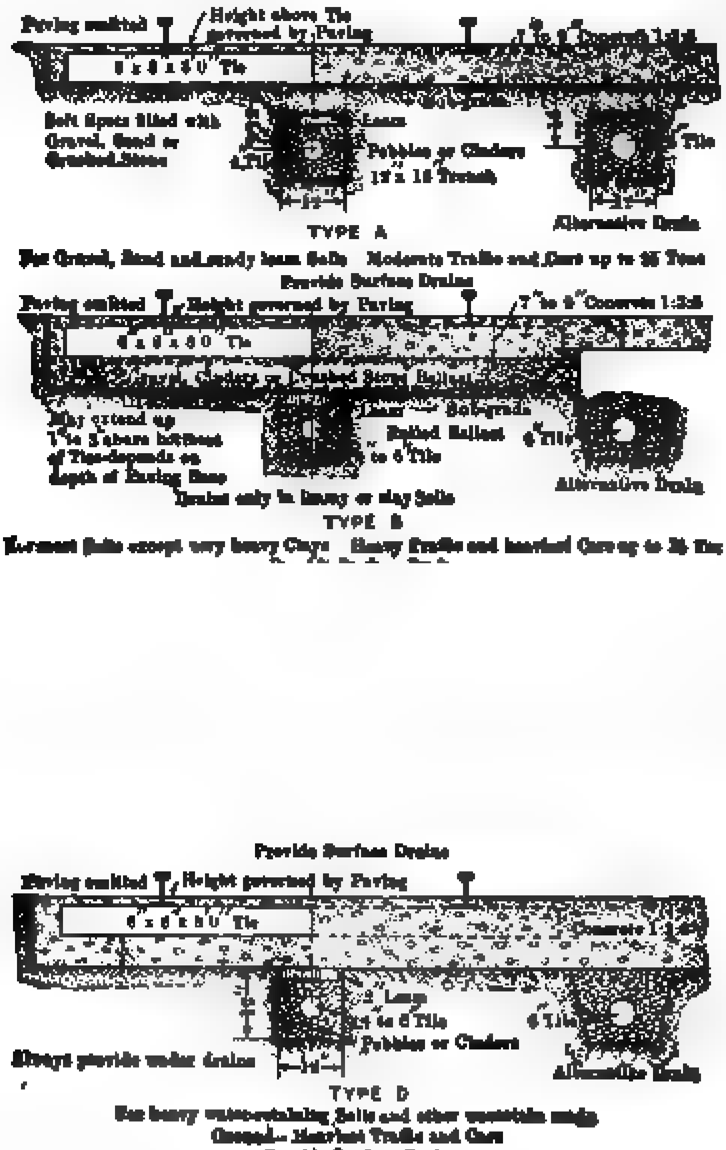

Fig 65

Rail Joints. "The old saying that the life of the joint is the life of the rail" still holds good. It might be extended to include the life of foundation and pavement, as poor joints not only cause rapid destruction of the rail ends but also of the foundation and pavement. The joint question has received much careful study within the past few years, and it is thought that modern electric and cast welds, several combinations of riveted and welded, and at least one improved type of mechanical joint have been evolved which will at least keep joint maintenance down to a reasonable minimum. The general adoption of 60-ft rail lengths has also cut the troubles in two by the simple process of reduction in numbers. The object then is to secure that type of joint which will produce the effect of a continuous rail and at the same time be most available when cost, application and possible repair are considered, altho first cost should not entirely control."

Pavements. Regarding the pavement on the street, it is said that the greatest service to the structure, aside from its own particular duty of providing for vehicular traffic, lies in the waterproofing qualities, and every effort should be directed toward the usage of those pavements which will best prevent the infiltration of surface water. The report finally recommends the FOUR TYPES OF CONSTRUCTION shown in Fig. 65.

Fillers. As regards filler for the head of the rail, the report states that it is difficult to determine; that the general practice seems to be, where the paving block fits under the head of the rail, to pour a cement grout, usually of one part of cement to three parts of sand; where a mortar or plaster is used the proportion may be increased to four parts of sand; that in isolated cases cast-iron fillers are used, as well as wood in other cases; that the preference, however, seems to be in favor of brick, whether the standard paver or a certain type of special brick filler; that concrete block also finds some advocates, but not many, and that asphalt cement grout is used at times where cement grout is omitted.

SUBSURFACE WORK

6. Effect of Subsurface Work on Pavements

The greatest difficulty that an engineer in charge of street pavement repairs has is the replacing of the pavement over cuts made for subsurface work. Repairs necessitated by the wear and tear of traffic can be foreseen and planned for, but a street can be put in first-class condition to-day and to-morrow it may have several openings in it made by the ubiquitous and persistent subsurface companies. This often happens, too, in a new pavement, and there is nothing that is more discouraging to the engineer than, after he has worked hard to have a pavement laid in a first-class manner, to find it opened up in a short time by the subsurface companies. It is true that this is often necessary, but in many instances, by the companies using proper foresight, a large amount of this could be avoided.

Location of Subsurface Work. It is the practice in this country to construct all subsurface work between the curb lines, in the place where it is most difficult and most expensive to connect with, and make repairs to, these structures. About 1890, when a municipality had sewer, water and gas mains laid previous to the construction of a pavement, it could rest assured that not many openings would be made in the pavement in the first few years, especially if the house connections were also laid; but when there exist in city streets, in addition to the foregoing, conduits for electric light and telephones, refrigerating lines, pneumatic tubes, and so forth, new work and repairs keep the streets torn up nearly all the time. Then in our rapidly growing cities, where, as in New York, 20-story buildings are torn down and others of 30 stories erected, and with such structures as the Woolworth Building, with its 55 stories, and the Equitable Building, with its 35 stories, the latter covering an entire block, it is necessary in almost every case to enlarge the subsurface structures in order to supply the increased demand.

The Amount of Disturbance to city pavements due to the work of the subsurface companies is very great. For instance, in the City of Boston during the year ending Jan. 31, 1910, 13 597 permits were issued for the opening of streets for different purposes, and the length of the openings was 151 miles; this was in a total street mileage of 487. In the Borough of Manhattan, New York City, in 1911 there were 25 179 openings made of various sizes, in a total street mileage of 440; in 1914 the area repaved over trenches was 139 865 sq yd, equivalent to practically 8 miles of streets 30 ft wide. In the Borough of Brooklyn, New York City, during the year 1911 the Bureau of Highways relaid pavements over trenches made by plumbers and the different corporations of an amount equivalent to 7 miles of streets 30 ft wide. There were 21 225 openings in Brooklyn in 1914, equivalent to 5.83 miles of streets 30 ft wide. In the City of Chicago, in

the downtown district, in a total street mileage of 20.8, during 1913 permits were given for 4464 openings, making a total yardage of 49 547; while in 1914, in the same area, 1947 permits were issued, covering a yardage of 15 865. In the entire city in 1914, 39 430 openings were made, covering a total yardage of 197 150, or 11.2 miles of streets 30 ft wide. The foregoing quantities are startling, but it is undoubtedly true that the same relative number of openings are made in the other cities of the United States. It may be said that the cost of these openings as a whole is paid by the corporations and not by the city. This is true, but at the same time it is a destruction of property and falls upon the stockholders of the different corporations; and in these days of efficiency and economy it is necessary that everything possible should be done to conserve property, of whatever kind. It must be remembered, too, that the damage done to pavements by the openings is not simply the cost of relaying the pavements actually taken up, but damage is also done to adjacent pavement, which is subjected to an undue and abnormal wear.

European Practice. It is often said that the question of street openings is taken care of in a better way in Europe than in the United States. This is undoubtedly true, but it must be remembered, in the first place, that in almost every case the minor utilities in Europe are laid in the sidewalk area instead of in the roadway. As a general rule, it can be said that sewers and large water and gas mains are the only substructures laid between the curbs in nearly all European cities. Then, too, while European cities grow rapidly, and some of them as rapidly as those of America, they grow in an entirely different way; that is, when a portion of a city is completed, it remains so practically for all time, so that the growth of the cities is from the center outwards, rather than an intensified growth in the center, as is the case in the United States. It is very seldom that buildings are torn down there except when they become old.

Number of Openings. Many openings, however, are made in the city streets of Europe. The Engineer of Westminster, London, informed the writer in 1913 that approximately 20 000 openings were made during the year in 100 miles of streets; about one-half of these openings were made in the sidewalk area and the others in the roadway. He also stated that the minimum size of sewer being built in Westminster was 2 ft 4 in by 3 ft 6 in, so that a workman could enter the sewers when a house connection was necessary and tunnel from the street to the house without in the least disturbing the pavement; also that when openings were concreted just previous to the replacing of the pavement, the concrete foundation was allowed to set 7 days before the pavement itself was relaid. This was true even on the Strand, which is probably the busiest street in Westminster. In Liverpool, in 1912, pavement was restored over 43 miles of trenches in a street mileage of 466, at a time when practically no building was going on. In Glasgow the total number of openings in the street pavements for the year ending May 31, 1912, was 8582, in a total street mileage of 245. In Edinburgh, with its 184 miles of streets, about 5000 openings are made per year. It was not possible to obtain information on the Continent as to the number of street openings, but in Berlin they were said to be negligible. A great deal of time and study has been given to the problem of so constructing subsurface work that its care would not cause such great disturbance of the pavement, but nothing practicable has as yet been worked out in America.

7. Pipe Galleries

New York City Practice. When rapid transit subways were contemplated in New York, the Rapid Transit Board adopted a general plan of construction for pipe galleries in connection with subway work, thinking in this way to obviate some of the trouble. The pipes and conduits to be dealt

with were those of the Department of Water Supply, Gas and Electricity, the mains of the New York Steam Co., the subways of the Consolidated Gas Co., the tubing of the Edison Electric Illuminating Co., and the tubing of the Western Union Telegraph Co., as well as the structures of the Bureau of Sewers. During the year 1896 the companies before mentioned were consulted and satisfactory conclusions reached concerning the location of their structures in the pipe galleries. In 1897 the Rapid Transit Board abandoned its previous work, substituting new plans, which, except as to enlargement at street intersections, provided for galleries of much the same type as the original plans. According to the new plans, an estimate of $650 000 for 2½ miles of construction on Elm St. and Fourth Ave., between Worth and 33rd Sts., was submitted in 1900. After these plans, specifications and details were prepared, the Sewer Bureau objected to its structures being included in the scheme. Its protests were based on the fact that the location of the sewers and the number of other structures above them not only rendered the sewers inaccessible, but made house connections excessively expensive. At the same time the Bureau recommended that the pipe galleries as planned should not be built.

The objections of the Sewer Bureau were later added to by those of the Department of Water Supply, Gas and Electricity, which, while approving the principle of pipe galleries, objected to the size as planned and to having water pipes in the same compartment with gas mains. The gas company had at various times raised objection to having its pipes in any confined space, claiming that such a condition was always dangerous, and, where electrical wires were also present, was especially so. The Chief Engineer of the Rapid Transit Board, on account of these objections, reported that the restoration of subsurface structures at the sides and over the roof of the subway would be possible, and consequently the construction of the pipe galleries was abandoned. At the request of the Merchants' Assn., however, the question of pipe galleries for lower Broadway, Manhattan, was revived in 1902. After much opposition had been presented, including that of the Rapid Transit Subway Construction Co., which objected on the ground that the travelling public would constantly be in danger, it was decided that the galleries should not be built. In 1906 the Rapid Transit Board advised its Chief Engineer to include gallery construction in all work then being planned, and, when in 1907 the question of abandoning certain galleries arose, advised their retention. The year following, approximately 3½ miles of subway construction, all of which provided for pipe galleries, was contracted for. Altho the Rapid Transit Board had at several times considered the combined construction of subways and pipe galleries as applied to various local conditions, the only gallery completed was a stretch of some 2500 ft on Delancey St. Owing to the objection of the gas company to galleries in general, and the objection of the Department of Water Supply to having its structures in the same compartment with gas mains, these galleries have never been used. The Public Service Comm., which succeeded the Rapid Transit Board in 1907, early took up the question of pipe galleries. On the Fourth Ave. subway, Brooklyn, 63 blocks of subway, including 33 000 ft of pipe galleries, were contracted for, and the excavation of the subway prism was started in such a manner that the galleries would be accommodated. However, before the time to begin the construction of the galleries, it was decided that they should be omitted, and in the plans for other portions of the dual system of rapid transit the Public Service Comm. did not provide for pipe galleries.

Chicago Practice. The question of pipe galleries is a matter that has been given a great deal of consideration in Chicago, and on Dec. 31, 1914, Alvord & Burdick, civil engineers, of Chicago, made a progress report to the Commission on Downtown Municipal Improvements on improved means for accommodating pipe utilities in the downtown Chicago streets. In the report it is stated that, as far as the downtown district is concerned, the street congestion below the surface is now comparable with that above the surface, and that it is not sufficient to provide for a greater occupancy

of the business district by improved transportation facilities without providing the means for the convenience of the greater population as provided by the utilities of water, sewerage, gas, electricity and telephone. It is also stated that naturally each utility company, seeing more clearly the cost to which it would be subjected by a change, and less clearly the costs that might be incurred by combination with other utilities, should incline toward solving its own problem for itself, but that for each utility to solve its own problem independently will not work to the best interests of the public, for the public is composed of individuals who to a great extent are rate-payers to all the private corporations and tax-payers as well. So that it was considered the investigation so far made was not sufficient to answer the fundamental questions of practicability and cost, but that the subject should be pursued without delay until these questions are settled.

Financial Problems. In the part of the city studied, that is, north of 12th St. and south and east of the River, there were 20.8 miles of pavements, and beneath these pavements 220 miles of utility pipes and conduit lines, not considering service connections. It would seem, therefore, that there was an average of 10 miles of subsurface structures of some kind to each mile of street. The report says that the utility galleries, to be financially practicable, must permit of a saving sufficient to warrant their cost, and further: "The savings will include: (1) Cost of street openings amounting to $200 000 to $400 000 annually; (2) a reduction in the cost of pavement maintenance; (3) a longer life for pavements; (4) a reduction in the operating cost of utilities; (5) a saving in cost of future extensions; (6) a reduced leakage of water and gas; (7) the value to the public of good streets and decreased interference with travel. The costs will include the fixed charges on: (1) The expenditures for galleries; (2) the cost of moving the utilities to the galleries, taking into consideration that the greater part of the present investment would be economically abandoned; (3) the cost of cutting and reconnecting the service lines. The costs and savings involved can be determined only by further investigation, and preferably thru coöperation with the public service companies. A rough estimate indicates that the reproduction cost of the sub-street utilities, public and private, now existing, lies between 10 and 13 million dollars." This report was made because of the fact that a great many of the streets in this section of Chicago are to be torn up for construction of transportation subways.

Character of Public Utilities. The 220 miles of pipes and conduits in this section are made up as follows: Water pipes, 34.6; sewers, 23.6; clay wires, 5.3; gas company mains, 94.9. Conduits of: Commonwealth-Edison Co., 25.3; Chicago Telephone Co., 24.2; Western Union Telegraph Co., 5.7; Postal Telegraph Co., 6.5.

Housing of All or Part of Public Utilities. The report further states that in considering the plans for housing the public utilities within a subway or underground gallery the question of providing for all or only part of the utilities should be taken into account. The cross-sectional areas of the utilities in certain streets are given, the greatest being on Twelfth St., east of State St., 31.6 sq ft, and a table is given showing how much these different areas would be reduced by excluding the sewers or gas mains, or both. It is concluded that a space 4 ft wide by 7 ft high would be necessary for inspection and repairs; that, even on straight runs where 15 ft would be necessary to house all the utilities, and where 5 sq ft only would be necessary for the same purpose with the gas mains and sewers excluded, means of access would require cross-sections not less than 45 sq ft in the first case and 35 sq ft in the second case, so that, so far as straight runs of conduit are concerned, the saving in cost by the exclusion of certain utilities would not be very great. It is also stated that: "There are other reasons, however, why careful consideration should be given to the exclusion or inclusion of certain utilities. The sewers, except for occasional new connections from premises served, require very infrequent tearing up of the streets, and the other utilities differ in the gain that would come from enclosure within a gallery, except in so far as concerns future enlargements. It is questionable whether a plan could be worked out whereby the electric cables could be accommodated otherwise than within ducts within the gallery with special facilities for admitting the cables at certain intervals. It might be practicable to accommodate the telephone cables

upon shelves or in troughs so that a man could make repairs by removing the cable and laying it upon the floor of the gallery."

Subway Congestion. The following conclusion is given for the relief of subsurface congestion, and is discussed in the report in detail: "The most obvious remedy for the relief of subsurface congestion in the Chicago streets, and the manner most frequently discussed, is the construction of underground subways or galleries permitting of the orderly accommodation of the necessary distribution pipes, conduits and wires. This remedy has been frequently discussed in a number of American cities, and the matter has been given quite a thoro consideration in the more congested cities of Europe. So far as this country is concerned, no actual experience in the matter has been gained; no such subways have been built except for one short street in New York, and, for some reason not fully apparent, this subway is not occupied.".

Sidewalk Space. The following is taken from their discussion as regards sub-sidewalk space: "It is believed that there is ample space between the curb and the property line for the accommodation of utilities on nearly all streets. The utilization of this space for the accommodation of public utilities has several important advantages. It surrounds each block, and therefore intersects the service connection for each utility at the place where new connections can be made with the minimum of expense and with least disturbance to continuous service. This applies to the private consumers and also to the public in forming a ready means of connection to existing fire hydrants, street drainage inlets, street lighting and the police and fire alarm boxes. It is also the location where a continuous passageway, except for street crossings, could be formed at a minimum of expense, for at least one side, and the roof of the necessary passageways is already built on two-thirds of the street frontage in the down-town district, and a greater percentage in that portion of it most needing utility galleries. The necessary construction could be carried on in this place with less interference to the public than in any location except in the alleys. All utilities except the sanitary sewers may be readily accommodated at or above the level of the cellar floors. If the separate system of sewers is adopted, the storm water drains at the upper ends of the branches may lie close to the level of the gutters, and even at their outlets need not be much, if any, below the basement floor level. The very great majority of the sanitary sewage will be intercepted at or above the level of the first basement floors. In the multi-story basements of the most modern buildings the sewage must be pumped with any practicable location of sewers."

European Practice. In 1910, Nelson P. Lewis, Chief Engineer, Board of Estimate and Apportionment, New York City, made a report (6a) on the subject of subways in European cities, and the following information is taken from that report:

London. In 1861 a pipe subway was constructed in Garrick St., 300 ft long. This subway was 7½ ft in height and 12 ft in width, in addition to which there were 14 arched side passages for house service pipes. In the creation of Southwark St., on the south side of the Thames, in 1864, Commercial Road in 1868, Queen Victoria St. in 1870, Northumberland Ave. in 1876, and other subsequent improvements, provision was made for the inclusion of pipe subways in the original construction of the streets. The cost was therefore reduced to a minimum, that of subways approximately 12 ft in width and 7 ft in height having varied from $17.08 a lin ft in the case of Garrick St., to $40.00 a ft in the case of Rosebery Ave.

The pipe subways in the City of London are partly under the control of the London County Council and partly under that of the Corporation of the City of London. The length of the subways under the control of the London County Council is 35 940 ft. The rates charged for the use of these subways are arbitrary and not always in proportion to the length of the subways. This is particularly true in the case of small pipes, the annual charge for those under 3 in in diameter being $5 for the subway in Garrick St., 300 ft long, as well as for that in the Victoria Embankment, which is 6690 ft long. For pipes 3 in and under 6 in in diameter the rate is $10 for the Garrick St. subway, and $25 for the Victoria Embankment, so that, altho the latter is 22⅓ times as long as the former, the charge for its use is but 2½ times as much. As the sizes of the pipes increase, however, this discrepancy in great measure disappears. For instance, for pipes over 36 in in diameter the annual charge for the Garrick St. subway is $15, while for the Victoria Embankment it is $250. The foregoing rates

are the "annual charge for water and gas companies having power to break up streets." A sharp distinction is drawn between companies having this power and other "companies, bodies or persons," for which latter the charge for occupying the entire subway appears to bear some relation to its length and is also at a higher rate. For this class of pipes the annual charge for those under 8 in in diameter for the Garrick St. subway is $10 and for that under the Victoria Embankment $150, while for pipes between 12 in and 18 in in diameter the annual charge for the Garrick St. subway is $25 and for the Victoria Embankment it is $420.

The subways under the control of the CORPORATION OF THE CITY OF LONDON occupy 15 different streets and have a total length of 8124 ft. In these subways there are 10 194 ft of water mains, 12 689 ft of gas mains, 5 049 ft of hydraulic power pipes, and 9 389 ft of pneumatic tubes. In addition to these pipes there are 34 416 ft of electric conduits, varying from small single cables to troughs, or boxes, 6 by 36 in, and including 168 ft of conduit in trenches beneath the bottom of the subways. The schedule of charges for the occupation of subways under the control of the Corporation of the City of London is the same as that fixed by the London County Council for water and gas companies having power to break up the streets. There is no schedule for other companies. The report says: "From the data already given it will be seen that the total length of pipe subways now in use in the City of London is 6.346 miles, altho London began building these subways in about 1861. In explanation of the very limited mileage which had been constructed, I was informed that it is only when a new street is created or an old street is widened or straightened that any attempt is made to build pipe subways, and that the expense of constructing them in existing streets simply for the accommodation of underground structures would be so great as to be out of proportion to the benefits to be derived."

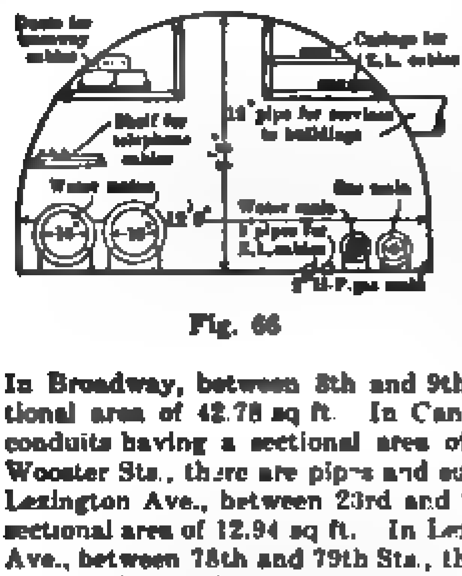

Fig. 66

Comparing the SPACE OCCUPIED by the London subways with the cross-sectional area of the pipes and conduits in New York, Lewis says that he selected three typical subways in the busiest streets of London, all being 12 ft in width and 7½ ft in height. The subway under Holborn Circus contains pipes and conduits with a sectional area of 5.88 ft. In Monument St., the total sectional area is 8.1 sq ft. In the conduit under Shoe Lane the total sectional area occupied is 9.83 ft. In Broadway, New York, between Walker and Lispenard Sts., there are pipe subways having a total sectional area of 46.3 sq ft. In Broadway, between 8th and 9th Sts., there are pipes and conduits having a sectional area of 42.78 sq ft. In Canal St., east of Mulberry St., there are pipes and conduits having a sectional area of 26.88 sq ft. In Canal St., between Greene and Wooster Sts., there are pipes and subways having a sectional area of 42.53 sq ft. In Lexington Ave., between 23rd and 24th Sts., there are pipes and conduits having a sectional area of 12.94 sq ft. In Lexington Ave., between 78th and 79th Sts., there are pipes and conduits having a sectional area of 17.85 sq ft.

Fig. 66 shows a cross-section of one subway constructed by the London County Council, and Fig. 67 the one constructed in the Victoria Embankment. These cuts are taken from the report of L. A. Dumond, of Chicago, made to the Commission on Downtown Municipal Improvements.

Nottingham, England. This city in 1910 had a population of about 250 000 and had constructed pipe subways in new streets since 1861 aggregating about ½ mile.

Fig. 67

Gas and electric conductors, as well as other pipes and mains, are placed in the subways, and the sewer constructed beneath the center of the subway, which is 10 ft in width and 8 ft 6 in in height. This subway cost, not including the sewer, subway

vaults, or connections, about $17 per lin ft, the work having been done in connection with the construction of a new street. In the report a quotation is made from a paper presented by the Borough Engineer, which reads as follows: "To show the value of such works in the street called Victoria St., in which is situated the general post office, there are, besides the gas and water pipes and connections, no less than six pipes containing telegraph wires in this subway, and not one single stone was disturbed in this carriageway for 25 years, and in that period not one single penny was spent in repairs on the street."

St. Helens, England. In 1910 it had a population of about 95 000 people. It has constructed a subway 6 ft 6 in in height, 5 ft 6 in in width, and 2040 ft long. It is constructed entirely of concrete, with the exception of one ring of brick on the inner side of the arch, the upper part of the concrete forming a foundation for the pavement of the street. It is provided with 6-in earthenware pipes, running beyond the curb line at frequent intervals, in which the gas and water service pipes are placed. The cost of the work, including lateral connections and electric light, is said to have been less than $12 per lin ft, but the work was done in connection with the entire reconstruction of the street. The Engineer stated in a personal interview that so far as he knew not a paving stone in the roadway of the streets occupied by the subway had been disturbed since its construction 11 years before. He regarded it as a success, but as expensive, and stated that there was no present likelihood of the construction of any more subways unless it might be under similar circumstances and in connection with the building of a new or the widening of an existing street.

Glasgow. This city has a subway 345 ft long, 6½ ft wide and 7 ft high, constructed in 1905. Seventy-three cross-connections, consisting of 12-in fire-clay pipe, were laid from the subway to the curb line, and the cost complete, including the connections for the service pipes and electric lighting, was somewhat less than $18 a ft. This subway was not built in connection with street reconstruction, which probably accounts for its increased cost over the subway of practically the same size at St. Helens.

Milan. This city has one street, the Via Dante, where subways have been constructed on each side 6 ft high by 4 or 5 ft wide. These subways are laid adjacent to the foundation walls. Lewis states that when he visited the city in 1910 one side of the street was open for a considerable portion of the length occupied by the subway for the purpose of laying a new gas main, but he was unable to ascertain whether this was on account of the lack of room in the subway or doubt as to the safety of placing a gas main therein.

These are all of the European cities that have specially constructed pipe subways, and the total length, exclusive of Milan, which is not given, is practically 10 miles. They have required more than 50 years for their construction, and they have been constructed, with the exception of Glasgow, only in connection with the laying out of new streets or the reconstructing of old.

Physical and Financial Problems. In considering the general subject of placing all underground conduits in subways it must be remembered that there are two problems to be studied, physical and financial. In all of our large cities underground structures have already been laid, and the problem of dealing with them is very different from what it would be were one about to plan a new city; and even then the experiences in New York, in attempting to combine them all in one subway, would indicate that the problem is not a simple one. The different corporations are jealous of their own interests, and it is extremely difficult to harmonize them so that they can be treated as a whole. If all underground construction work were owned by the city, then the problem would be simply a question of finance, as, if it were deemed advisable, the different departments could be directed to lay their pipes as the authorities deemed best. It seems extremely improbable that it will be possible to arrange in a practical way for the grouping of all subsurface work in one or more subways in the same street. Admitting, then, this to be so, the question is to handle the making of repairs and the work of new construction in such a way as to inconve-

nience the public and damage the pavements as little as possible. That can be done by requiring that all subsurface work shall be carried out in accordance with certain rules and regulations. It should be understood that the streets are for the use of the public and that if it is necessary for any corporation to obstruct them such corporation should be willing to bear considerable expense and inconvenience so as to protect the public. Rules can be made that a pavement shall not be opened for a certain length of time after it has been laid, but when leaks occur in sewer, gas or water mains they must be repaired or the pavements will be damaged more than if left alone.

8. Prevention and Restoration of Pavement Openings

Admitting that pavements must be opened frequently, the problem is to reduce the number of openings to a minimum and so safeguard them that there will be as little obstruction to traffic as possible. Precautions relative to the prevention and restoration of openings are absolutely necessary in the built-up sections of cities where mains of various kinds have been laid and no records kept of their location, but in the growing sections of a city there is no necessity of new construction being placed between the curbs. The city owns the street from property line to property line, and the sidewalk area can be utilized to a great extent for many subsurface conduits. It is particularly desirable, even in the suburban districts, to have the streets free from poles and the wires placed underground, but when this means that an opening shall be made in the street for every house connection and for necessary repairs, the gain is attended with considerable loss. It would seem that it would be perfectly feasible for the different subsurface companies to construct service mains in the sidewalk space, connecting at the end of the block with their mains, so that house connections could be made without interfering at all with the roadway surface. In Brussels electric lines are run to tall poles and from there to the different buildings, so that street openings are not often necessary. One sewer connection could be made to a main in the center of a block, and then the different houses could be connected with this sub-main. If objection were made to the fact that these different connections are maintained by the property owners, it could be said that their maintenance might be taken over by the city at less expense than the cost of the extra repair to the pavements due to openings for the connections. In some cases in the outlying districts at the present time the telephone wires are erected on poles placed in the rear lots on the property line and from there connected with the different houses. It would seem to be entirely practicable, if the matter were taken up by the city authorities and the different utility companies in the outlying districts, to construct their systems so that openings in the pavements could be reduced very much below what they are at the present time. Objection might be made by the companies that laying the pipes under the sidewalks would require two lines, but in each case they would be smaller and the expense of opening the street done away with, so that it is questionable if the ultimate expense would be any greater.

In Cincinnati, Ohio, an ordinance prohibits the tearing up of new streets within 3 years after the time of their construction, macadam roadways being excepted. The ordinance provides for 90 days' notice of contemplated street construction to property owners and to public service commissions and also to the director of public service, who is required to compel the laying of sewer and water pipes before streets are constructed. Failure

of the property owners to get notice of the proposed improvements or failure to put in the underground accessories in advance will not be accepted as an excuse for permitting them to tear up the streets after they have been built. The ordinance applies to all streets to be improved after its passage which are not already under construction. The measure also provides that if property owners do not have service connections laid from the sewer and water mains to the curb the city will have this done and collect the cost from the property owners in the same way that sidewalk assessments are collected.

New York City. Probably no other city in the world has a greater maze of substructures in its streets than the City of New York. These substructures consist of sewers; water mains; gas mains; elevated column foundations; conduits, conveying electric current for light and power; telephone conduits; conduits conveying electric power for the operation of the various surface railroads; mail tubes thru which mail is distributed by compressed air to the various railroad terminals and the substations of the general post-office; police and fire alarm conduits; conduits conveying the inshore ends of the transatlantic cable lines; steam pipes of the New York Steam Co., conveying steam for heat and power; refrigeration pipes; pipe lines of the oil companies; vaults under the sidewalks; private tunnels, connecting properties on opposite sides of the streets, conveying light, heat and power, etc. Substructures of this character have been accumulating for years in the principal thorofares in this city, and, unfortunately, little is known relative to their location or size. In consequence, it has become a fixed practice, preliminary to the installation of new structures, to resort to pavement mutilation by digging test pits in order to determine a feasible location. These test pits are dug at intervals of about 100 ft, and frequently pavements on several thorofares are mutilated in this manner before a satisfactory route is determined. This mode of procedure is at best only a makeshift as long as the intervening space remains a mystery. When the work is in progress and this space is uncovered it is not unusual to find unlooked-for structures of such importance that to avoid them special construction must be resorted to. This practice delays the work, keeps the thorofare obstructed for a greater length of time, results in additional pavement mutilation and increases the cost. The most important subsurface work ever carried on in this city was the construction of the elaborate system of passenger-carrying subways, which in many instances occupy the entire width of the streets. Provision had to be made for practically all substructures encountered; in consequence, it was necessary to prepare subsurface record maps in advance of the work. These subsurface records were used in connection with the actual designing of the structures and were made a part of the contract drawings, giving the prospective contractor much valuable information as to the type and character of the substructures to be cared for during construction. This, without doubt, resulted in a material saving in the cost of the work. In New York City the Board of Estimate and Apportionment will not authorize the paving of any street unless water and gas mains and sewers have been constructed. In the Borough of Brooklyn, the Sewer Bureau includes in its work for the sewer proper the laying of house connections within the curb line in front of each lot.

Borough of Manhattan. The following rules have been adopted to be observed by parties making openings in the pavements, it being recognized that when openings are made they must be repaired as soon as possible.

"The Applicant Agrees to comply with all the rules and regulations printed upon the back of or referred to in this application, as well as all other laws and ordinances relating to such work; and the acceptance of the permit shall be deemed an agreement to abide by all of its terms and conditions as herein set forth.

"Deposit. A public service corporation may make a cash deposit or give a bond and make an additional smaller cash deposit in advance, an amount which in the opinion of the Commissioner of Public Works shall at all times be sufficient to cover all expenses to the city as above set forth; provided, however, that the Commissioner of Public Works may discontinue such arrangement at any time and require a specified charge for such opening. The City of New York shall not be liable for any interest on deposits made as provided in any part of this permit.

"Yardage Rate. The charge shall be based upon an arbitrary rate per square yard. Should a settlement occur in the restored area or other defect develop therein within 6 months from the date of restoration, which in the opinion of the Chief Engineer in charge, after proper notification of and conference with the permittee, was due to improper workmanship below the pavement itself, the Borough President, on behalf of the City of New York, will again replace the restored pavement, the cost of such restoration to be charged against the permittee.

"Time Limit. In case the work has not been completed before the day of expiration as shown in the permit, the Borough President may, if he deems necessary, take steps to backfill the trench and replace a permanent pavement over the opening for which the permit has been issued; and if an extension of time beyond said date is needed for the completion of the work, a new application must be filed.

"Subsurface Plans. Upon the completion of the work the permittee shall furnish to the Commissioner of Public Works plans of such character as he may direct, showing accurately and distinctly the location, size and type of construction and complete dimensions of the structure installed. The depth below the street surface of the new structures must be shown; also their location with reference to the nearest curb line and curb intersection. No refunds will be allowed by the Commissioner until such plans have been submitted.

"Excavation. The work shall be so conducted that the water mains or service connections, the sewers or house connections, shall not be interfered with. All rock within 5 ft of a water main shall be removed without blasting. No excavation shall be made within 4 ft of the trunk of any tree without the approval of the Park Commissioner.

"Backfilling. The applicant further agrees to replace, as far as possible, all material excavated, making use of flushing, tamping or other means to accomplish this end, and supplying any deficiency; and that in case the inspector shall deem the material unsatisfactory for backfill, and this decision shall be concurred in by the Chief Engineer of the Bureau of Highways or duly authorized assistant, then the applicant shall backfill the trench with sand, hard-coal cinders or other proper material, removing all excess of original material from the premises. If tamping alone is employed, the material shall be replaced in layers not to exceed 3 in in thickness, each layer being tamped so as to be as thin as possible.

"Planking. Upon completion of the backfill, the applicant further agrees to lay in the cut in the pavement temporary planks of suitable thickness and quality, all securely fastened together, or, if permitted in writing, other material satisfactory to the Commissioner of Public Works, such as hard-coal cinders wetted and heavily tamped, all properly supported so as to bring its top flush with the pavement surface.

"Final Restoration. At the time of making the repair the concrete base shall be removed for a space at least 6 in larger on all sides than the dimensions of the trench excavated, all old concrete work to be properly grouted, and fresh concrete laid so as to secure a good bond with the old concrete and a firm foundation on the untouched sides of the trench. The portion of the pavement which rests upon the new foundation shall be replaced by the city over an area 6 in larger on all sides than the area of the new concrete above described; all of such work being done in order to secure a proper bond and to prevent improper settlement.

"Notice to Bureau of Highways. The Bureau of Highways shall be notified 4 working hr before the time when the opening of the pavement is to be made, so that an inspector of the Bureau may be present, and until such proper notification has been made no opening in the pavement shall be undertaken unless special permission,

in writing, is given by the Borough President to make such without the presence of an inspector. The Bureau of Highways shall also be notified 4 hr before completion of backfill so that proper orders may be issued for permanent pavement replacement. If, after proper notice has been given the Bureau of Highways and acknowledged by it, an inspector has not visited the work, the permittee may proceed therewith."

The Borough of Brooklyn is one of the largest boroughs in the Greater City of New York, with an area of 77 square miles, a population rapidly approaching the 2 000 000 mark, a highway system of practically 1200 miles and 900 miles of sewers. Municipal authorities for years have recognized the necessity of a more systematic control of subsurface conditions, and during the latter part of the year 1906 a moderate appropriation was obtained by the President of the Borough of Brooklyn, to be used in establishing a Division of Substructures, to be attached to his office.

Work of the Division of Substructures. The work was put in charge of a competent engineer, with the following objects in view:

1. Accumulating all information obtainable as to the size, location and character of structures under the streets and avenues of the Borough, and recording the same on durable maps.
2. Assigning definite locations for new substructures.
3. Reducing pavement mutilation to a minimum.
4. Conserving as far as possible for future utilization subsurface spaces which are rapidly becoming one of the city's most valuable assets, and from which substantial revenues will be derived thru future franchise grants.
5. Furnishing to applicants seeking subsurface space for tunnels, pipe lines, etc, information as to the location and size of existing substructures. Such information is required by the Board of Estimate and Apportionment when applications are filed for franchises.
6. Furnishing other city departments with information to be used in connection with the location and construction of subways, sewers, water mains, etc.

Details of Record Maps. Preliminary to preparing the subsurface record maps it was decided to adopt a system whereby the maps could be prepared in any section of the Borough without consequent confusion and duplication. The large area to be covered was divided into twenty sections and each section treated separately. The sections are numbered 1 to 20. Record maps are plotted on a durable cloth-mounted paper in sheet form, 32 in wide and 42 in long, to a scale of 20 ft to the in. These dimensions provide amply for a city block length of 800 ft and are the maximum size sheet that can be readily handled. The next step was a systematic arrangement of record maps so as to cover economically a section or part of a section. In other words, the preparation of a record map layout. This was accomplished by using templets of tracing cloth and applying them to a large-scale city map. The city atlas drawn to a scale of 100 ft to the in was used. Tracing-cloth templets cut to a scale of 100 ft to the in correspond in size to the record maps which are plotted to a scale of 20 ft to the in. Consequently, the area covered by a templet on the city map is the same as the area covered by a record map on the ground. With care and ingenuity excellent results are obtained and a record map layout is prepared, using the minimum number of maps to cover a given area. The outline of the streets in the area to be covered by the record maps is inked in on the templets and they are laid aside for future use, which shall be described later. With this method it is possible to make subsurface investigations, prepare record maps in any locality, and obtain a systematic record of such operations. The record maps are numbered consecutively in accordance with the section in which they are located, that is, a record map numbered 1–25 would mean that it is a record of subsurface investigations taken in section No. 1, over an area covered by record map No. 25. This system of section and record map numbering permits of a comprehensive filing system, as all information is filed in accordance with its section number and record map number. In sections of the Borough where the street system is extremely irregular and made up of two or three rectangular systems cut thru by an important diagonal thorofare, a record map layout is determined, covering the important thorofare. The problem presented in

making this layout is to cover by not more than one record map complicated street intersections, thereby avoiding splitting up these intersections, which would necessitate plotting part on one record map and part on another. With a determination of a systematic layout covering this thorofare, a layout is next determined for the adjoining rectangular systems, which usually presents but few difficulties.

Surveys and Investigations. Upon the completion of a record map layout, surveys and investigations are made on the ground. The surveys are made from the established base lines and include the location of curb lines, building lines, car tracks, hydrants, manhole covers, corner basins, gas drips, elevated railway columns, poles and, in fact, any object on the surface that will serve as a guide in determining the size and location of the underlying structure. These locations are obtained by right-angle offsets from the base lines. The stationing of the offset points on the base line is determined by the use of an optical square. This small instrument has proven to be a great time-saver. Upon the completion of the survey within the area covered by the record map or maps to be prepared, investigations are made of all manholes. The usual procedure is to investigate sewer manholes and appurtenances first. Using a specially designed sewer rod, the depth and size of the sewer is determined from the street surface and the type of construction and condition noted. The corner basins are surveyed in a similar manner. It is often necessary to flush corner basins from the near-by hydrants to determine, particularly at street intersections, into which sewer they empty and obtain an approximate location of the connection. Unfortunately, the records of sewers constructed in the older section of Brooklyn years ago are in some instances missing and in other instances so incomplete as to be of no practical use. The manholes of other structures are taken up in turn, the iron covers removed, and full measurements taken, showing the location and size of the conduit line or pipe line entering and leaving the manhole. In the case of the large manhole or junction boxes of the electric companies a special extension rod is used for taking the various measurements. By use of this rod it is possible to obtain practically all the measurements from one position in the center of the manhole. These investigations afford a fund of accurate information as to the size, depth below the surface, and location of substructures at frequent intervals in the thorofare under investigation. The direction taken by pipes, conduits, etc, between manholes is often disclosed by the outline of a strip of pavement relaid after the installation of a new structure or repairs to an existing structure. Locating these traces of pavement cuts is part of the work of the survey party. All irregularities, such as broken manhole covers, clogged sewers or corner basins, broken hydrants, gas-laden junction boxes, etc, are noted and brought promptly to the attention of the city department or public service corporation responsible. While these surveys are under way a representative is sent to the offices of the different public service corporations and city departments for all information obtainable relative to substructures maintained by them in the city thorofares. This information includes test-pit records, general location of structures, standards of construction and plans of special work installed over the area under consideration. The record maps are then plotted. The maps are laid out in strict accordance with the outline of the area to be covered as shown on the templets previously referred to. The survey notes are accurately plotted and checked, including all information from the offices of the public service corporations and city departments. The plotting of these maps is the most important part of the work, as it involves so much troublesome detail. All surface locations, such as building and curb lines, trolley tracks, manhole covers, etc, are shown in black, while the various substructures are shown in distinctive colors: electric light and power conduits are shown in red, gas pipes in green, water pipes in blue, telephone conduits in brown, etc. In consequence, it is not a difficult matter to trace out a run of any particular pipe or conduit line. Water colors are used for the reason that it is necessary from time to time to make corrections to conform with changes constantly taking place, and erasures can be made with but slight injury to the paper.

All Applications for Permits to make new installations and repairs to existing structures are referred to the Division of Substructures for criticism, prior to the issuance of permits. In this way the engineer in charge is kept in close touch with such work, and pavement mutilation and interference with existing structures is materially reduced. During the progress of the work measurements are taken on the ground, relative to the location of the new structures, and all structures encountered. This

information is filed in accordance with the number of the section and number of the record map covering the area in which the work is located. If a record map has been prepared covering the area, the information is plotted by a draftsman assigned to the special work of correcting record maps, thereby keeping them up to date.

Locations and Drawings for New Installations. While definite locations are frequently furnished for new installations, much work has been done in connection with the preparation of subsurface drawings in advance of public work of importance, such as the construction of passenger-carrying subways, trunk sewers and the installation of large water mains. The subsurface information accumulated is used in preparing the construction plans and is also made part of the contract drawings. Probably the most extensive investigations were made in advance of the installation of the large water distribution mains, a part of what is known as the Catskill Water Supply System.

Value of Division. While it is a difficult matter to calculate dollar by dollar the saving involved by this systematic procedure, it is conservatively estimated that the saving is at least equivalent to the entire cost of the Division of Substructures to date. Excellent progress has been made. In the files of the department there has been accumulated a mass of information relative to other sections of the Borough, such as general locations of pipes and conduit lines, private tunnels, test-pit records and construction drawings. This information will be used when the final surveys of these sections are taken up. Similar departments have been established in the other boroughs of the Greater City, using the Brooklyn methods as a basis of operation.

Philadelphia. Undoubtedly, however, the most elaborate and effective steps in the direction of pavement protection have been taken by the City of Philadelphia.

Board of Highway Supervisors. In 1884 there was organized in that city what is known as the Board of Highway Supervisors under an ordinance passed in March of that year "for the purpose of preventing frequent and unnecessary openings in streets and street pavements; to promote system and economy in repaving over breaks made for underground work." The Board is composed of the Director of Public Works, the Chief of the Bureau of Highways, the Chief Engineer of Surveys, the Chief of the Bureau of Water, the Chief of the Electrical Bureau and the Chief of the Bureau of City Property. The Board is vested with full power, not only to grant original locations to companies authorized by law to lay pipes and conduits, but also to direct their removal and relocation whenever the public good may demand it.

Records and Plans. For the purpose of enabling the Board to act intelligently on applications, a recording and drafting department is maintained where all underground structures are plotted and their sizes, depths, distance from the curb or building lines shown upon plans of uniform size drawn to a scale of 20 ft to the in. Each structure is colored with a conventional tint so that it may be followed on the plans. The ever-increasing demand for space under the street surface makes it necessary that the available cross-section be utilized to the best possible advantage. This, in a measure, is accomplished by grouping the structures as closely together as possible. They are required to be laid in locations parallel with the street line and any continuation of existing work must be laid in the line of the original substructure. These extensions are borne in mind when locations are given for new structures. The accuracy of the records in the drafting room of the Board of Highway Supervisors is so to be depended upon that when sewers, water pipes or other underground structures are to be laid in the streets their location can be determined with sufficient exactness to admit of the perfection of the plans for the work without the necessity of making advance excavation. All applicants for permits to locate pipes, conduits and other subsurface structures are required to obtain plans from the Department records, showing by cross-sections all existing structures in the street. These plans are used by the Board in considering the applications and in fixing the locations. By this means an intelligent supervision is constantly kept of every class of construction placed under the surface of the streets, and the city, by reserving space which may be required in the future, obtains a maximum degree of utilization of the width of the street available for uses of this kind.

Charges for Plans. A charge per lin ft is made by the city to parties obtaining plans and information and the cash receipts are considerably more than sufficient

to maintain the force in the drafting room and the field inspectors, who are sent to see that the locations granted are followed, and to make systematical measurements and daily reports covering structures of every character met with in the excavation. From these returns the plans are constantly being checked, and, where necessary, corrected. In addition, upon the completion of the laying of any underground work, either the Bureau of the city or the private corporation having charge of same is required to return to the Board of Highway Supervisors a complete plan giving the exact location occupied and the sizes and positions of every kind of construction met with during the progress of the work. This gives a complete and valuable record for future reference. The charge for the information is as follows: For furnishing plan indicating all underground structures 5 cents per lin ft for any continuous length in the one street up to 2500 ft, 5 blocks, and 3 cents for each additional foot. Where locations are given on unpaved and macadamized highways a straight charge of 1 cent per lin ft is made on account of the fact that these highways are generally located in the suburban sections and contain but few underground structures. Upon the completion of the work, the Bureau sends an official to make a survey and record the exact location in which the structure is placed, and for this a charge of 2 cents per lin ft is made on every class of street, but in no case is this charge less than $5. That is, if a telephone company applies to the Board of Highway Supervisors for a plan showing the underground structures in a street, covering a length of 1000 ft, they would be charged at the rate of 5 cents per lin ft, or $50 for the plan, and upon the completion of the work the Bureau makes a complete survey of the location of the structure and all manholes, spurs, etc, for which the company is charged an additional 2 cents per lin ft, or $20, so that the total cost to the company for the stretch of 1000 ft amounts to $70; on the other hand, for a length of 5000 ft, the charge for the plan would be at the rate of 5 cents per lin ft for the first 2500 ft, or $125, and at the rate of 3 cents per lin ft for the remaining 2500 ft, or $75, making the total plan charge $200, while the charge for the survey would be at the rate of 2 cents per lin ft for the entire distance, or $100, so that the total cost to the company for the stretch of 5000 ft would amount to $300.

Present Status of the Board. The Board has been working for so long a time and in such detail that it has practically all of the subsurface construction in Philadelphia accurately plotted, so that it can readily assign to any applicant the best location for any new work. In this way the space in the streets is most economically used, as by this system nothing is done in haphazard way, but all structures are located according to a definite plan. The fees referred to at the present time create a fund sufficient to pay all the expenses of the Board, so that it is self-sustaining. Philadelphia is honored by being the pioneer in this work as well as for the results that have been accomplished.

Rules and Regulations of the Board of Highway Supervisors Governing Applications for the Laying of Electrical Conduits, Tubes and Manholes, adopted Nov. 8, 1906, and now (1918) in use:

Applications. Companies, corporations, firms or individuals applying under the general ordinance of Aug. 5, 1886, "regulating the laying and construction of underground wires, electrical conductors, conduits, cables and tubes in the City of Philadelphia," shall file with the Board of Highway Supervisors:

1. (a) An application, in writing, giving full name of company, corporation, firm or individual, together with amount of capital, business address, the names of officers and directors with address; (b) the purposes for which they wish to use the streets; (c) character of conduits, manholes, tubes, etc.

2. At least two copies on Linaura of plans, showing all existing underground structures and complete details of proposed construction.

3. Such other information as may be required to enable the Board to reach a clear understanding of the whole subject.

Agreements. Before any street surface shall be broken, or a permit issued, except as hereinafter provided, the following rules and regulations, and such additional rules and regulations as the Board of Highway Supervisors may from time to time adopt, shall be binding on the applicant or applicants:

1. (a) The execution of bond, etc, to comply with general ordinance; (b) compliance with the ordinance granting special privileges; (c) compliance with the rules of the Board of Highway Supervisors.

2. A certificate from the City Solicitor that the necessary bond and agreement have been filed.

3. A certificate from the City Treasurer that the requisite payments have been made.

4. An agreement from the Contractor, who is under liability for the maintenance of any street desired to be broken, stating that the guarantee will in no way be affected by the breaking of the same.

SPECIAL AGREEMENTS. After the approval of the Board of Highway Supervisors and the issuance of the permit, the terms and conditions of the application and the accompanying plans shall not thereafter be altered or departed from without the consent of the Board previously obtained; except that in cases of emergency, the Chief of the Electrical Bureau may authorize modifications when necessary, reporting his action to the Board at its next meeting.

2. Where a conduit crosses a bridge, a plan shall be submitted to the Chief of the Bureau of Highways, and no conduit laid thereon until such plan is approved.

3. On undedicated streets the consent of the owner or owners shall be first obtained, and affidavits to that effect filed with the Board of Highway Supervisors.

NOTICES. Before any street surface shall be broken, under a permit as above, notice must be given, in writing, by the receiver of the permit, to the Chief of the Bureau of Highways and the Chief of the Electrical Bureau, of the time, place and extent of the proposed breaking; and where a conduit is located on the sidewalk, the District Surveyor shall be notified of the location and the date of commencing the work.

CONSTRUCTION. 1. No portion of any new structure, when in place in the street, except such as is designed to form a part of the street pavement, shall be less than 2 ft below the surface of said pavement, except with the written approval of the Chief of the Bureau of Highways; and the tops of iron structures forming parts of the street pavement shall have a roughened surface with projections rising not less than ½ in, and spaced not more than 2½ in apart, as approved by the Board of Highway Supervisors. All manhole covers upon streets paved with asphalt, vitrified brick or wooden blocks shall be filled with asphaltum or other material to the satisfaction of the Department of Public Works.

2. New work and new structures shall not interfere with existing pipes, sewers, conduits, or other structures, or their connections, except where absolutely necessary, and then only with the previous consent, in writing, of the Chief of the Bureau having charge of such structures. Any modification of existing structures found to be necessary must be made by or under the direction of the Bureau concerned and at the expense of the party having the permit. All necessary supports and protections to existing structures must be promptly supplied by, or at the expense of, the party having the permit, and to the satisfaction of the Bureau concerned. The said party shall erect and maintain and bear the expense of all necessary guards and danger signals, furnish all necessary watchmen to protect the public and the work during its progress, assuming all liability for accident or damage to persons or property that shall occur in the course of or by reason of said work, and agree to save harmless the City, its officers, agents and servants in all such cases.

3. When, in the judgment of the Board, it shall be deemed desirable to employ one or more special inspectors to supervise the work, such inspector or inspectors shall be appointed by the Director of the Department having supervision over the same, and a sufficient sum deposited by the party receiving the permit, with the Chief of the Bureau, for the payment of such service.

INTERFERENCE WITH TRAFFIC. 1. Openings in streets shall be made at such times and places, and be supported and guarded in such manner as, in the judgment of the Chief of the Bureau of Highways, will least interfere with the rights and convenience of others, and interrupt the traffic of the streets no more than is absolutely necessary.

2. Material and tools for construction must not be delivered in the street till needed for immediate use, and then must be so placed as to cause the least interruption to traffic. Not more than 500 ft in length shall be obstructed or occupied at the same time without special authority of the Board.

FILLING OF OPENINGS. 1. All openings in streets must be promptly filled with suitable material, free from rubbish and perishable matter, and thoroly and evenly compacted thruout, by ramming in thin layers while being put in, or by puddling.

The pavement of street or foot walks must then be at once restored with the same character of material, equal in composition and color to match old work, in accordance with the standard specifications of the Department of Public Works, Bureau of Highways, for such class of work, and maintained in good condition, satisfactory to the Department of Public Works, during the time of any existing guarantee, or as required by Ordinance of Councils, but in no case for a less period than 5 years. All permits are issued subject to Ordinances of Councils regulating the paving and repaving of streets.

2. Surplus and condemned material must be removed, and the street cleaned and entirely restored, without delay.

MAINTENANCE OF SUBSURFACE STRUCTURES. 1. All subsurface structures and all surface structures forming part of the street must at all times be kept in good repair. All work and material used in restoring or repairing the street shall be satisfactory to the Department of Public Works, and when notice calling attention to needed repairs is given, it must receive attention within 24 hr.

2. All work and material used in the construction of electrical conduits and manholes must be satisfactory to the Chief of the Electrical Bureau, and any work or material condemned by him must be at once made satisfactory.

FILING PLANS. Immediately after the completion of the work, the party to whom the permit is issued shall file complete plans in detail to a scale satisfactory to the Board, showing the work as constructed, with all previously existing structures encountered during the construction of the work.

PROTECTION OF PUBLIC. Should work necessary to protect the public in the use of the street be omitted or imperfectly performed by the party holding the permit, then after notice the Chief of the Bureau of Highways may cause the work to be done at the expense of the party receiving the permit. Failure at any time to fully and faithfully comply with these regulations, and such further regulations as the Board may from time to time prescribe, or promptly pay such expense as hereinbefore or hereinafter authorized, shall at once work a forfeiture of permits issued, and debar the party from receiving any further permits until relieved by action of the Board of Highway Supervisors.

PERMITS FOR ELECTRICAL HOUSE CONNECTIONS for the construction of manholes on lines of underground conduits already constructed, where such construction is of advantage to the City or the betterment of the system, may be issued by the Bureau of Highways after approval by the Chief of the Electrical Bureau, without reference to the Board of Highway Supervisors. House connections shall follow the line of conduit and not cross streets diagonally.

If, in the LAYING OF WATER OR GAS PIPES, SEWERS, or any other municipal work, it shall become necessary to change the location of any of the conduits, manholes or other structures, they shall be shifted or altered at the cost or expense of the owners, to such places as shall be directed by the Board of Highway Supervisors.

2. Where the City constructs or reconstructs sewers, or lays or relays water pipes, the Company shall maintain its conduits.

DURATION OF PERMITS. No permit will be valid for more than the number of days specified therein, which shall be determined by the Board of Highway Supervisors at the time the permit is authorized; for any subsequent work a new permit must be obtained. Persons in charge of any work on the streets must have in their possession, at all times while so engaged, the permit issued by the Department. All permits shall expire on Dec. 31 of the year in which they are issued.

COMPARISON OF ROADS AND PAVEMENTS

BY

GEORGE W. TILLSON

CONSULTING ENGINEER TO THE PRESIDENT OF THE BOROUGH OF BROOKLYN, NEW YORK CITY

GENERAL DATA

PROPERTIES OF PAVEMENTS

PROPERTIES OF ROADS

METHODS OF COMPARISON

GENERAL DATA

1. Historical Development of Roads and Pavements

Variety of Pavements. Pavements have been laid of a great many different materials, both in their natural state and also combined so as to make an artificial product. There have undoubtedly been more variations in the forms of bituminous pavements than of any other kind, as many hundreds of patents have been taken out for pavements composed of asphalt or coal tar used in some peculiar or particular way. As has been stated

in Sect. 19, stone was the original paving material and used in many different ways. This was natural on account of its general availability and the knowledge of its durability. But so many experiments have been made that it is not possible or profitable to describe them all. Some of the unusual types, however, will be mentioned.

Unusual Types. IRON BLOCKS AND PLATES. On Unter den Linden, in Berlin, in 1877, an iron pavement was laid. This remained on the street until 1890, when it was taken up, and never used elsewhere. The same contractors received permission, in 1888, to lay impregnated wooden blocks capped with steel. The blocks were laid on concrete and the joints filled with some kind of bituminous material. This pavement lasted until 1897, when it was taken up by the contractors and replaced with rock asphalt. The pavement was said to have been fairly durable at first, but after being in use 8 years the steel capping was worn out in consequence of the traffic. The cost of this pavement was about twice as much as for rock asphalt, and, as the price of steel increased considerably after the pavement was laid, its continued use would have involved still greater expense. Iron blocks were laid on Cortlandt St., New York City, about 1865. They were roughened on the surface by hexagonal projections about 1 in in size, separated by similar depressions. This made a rough and noisy pavement, and horses tore off their shoes and slipped and fell frequently, so that after a short trial it was taken up and replaced with stone blocks. In 1885 a hollow iron block about the shape of the ordinary granite block was suggested, the hollow space to be filled with any material that the officials might deem suitable. Another plan was to set hollow iron cylinders closely together on a firm base and fill the interstices as well as the cylinders with concrete, the idea being that the iron would prevent the wear and the concrete give a general smoothness. It is doubtful, however, if this idea was ever carried out to any extent. In Columbus, Ohio, in 1894 an entrance to a railroad freight yard was paved with iron plates cast with pockets 3 7/16 in square on the upper side. Each plate contained 5 full, 4 half, and 4 quarter pockets, so arranged that when set on the street the plates were square and the pockets at an angle of 45° with the length of the street. The plates were bedded on the foundation, and into the pockets were driven oak spikes 5 in high and projecting 2 in above the pockets. At the end of 16 months the blocks showed a wear of about ¼ in. It is said that macadam within the freight yard was renewed in 90 days and sheet-asphalt outside was replaced in 4 months. This pavement, however, would not be practicable on a large scale and was used to a very slight extent.

COMPRESSED MARSH GRASS. In 1898 an experimental pavement of compressed marsh grass was tried in Richmond, Va. The grass was first treated with a preparation of oil, tar and rosin, and then compressed by hydraulic pressure into blocks about 5 in square and bound together with wire. The blocks were laid in the usual way on a street where they were subjected to very heavy traffic. The pavements lasted but a very few months.

GLASS. In 1898 an experimental pavement was laid in Lyons, France, the blocks being made of devitrified glass; they were 8 in square, each one being cut on top into 16 smaller squares so that the finished pavement looked very much like a huge checkerboard. The treatment consisted of heating broken glass to a temperature of 677° C (1250° F), and compressing it into molds by hydraulic force. The physical transformation of the glass is said to be due to devitrification under the Garchy process. This action, however, is more apparent than real, as a chemical analysis shows that after devitrification the glass has the same composition as before. It possesses all intrinsic qualities of glass except transparency. It is said to resist crushing and heavy frosts very much better than before being treated. No pavement of this character has been used to any great extent.

Classification of Pavements. During many years of experimentation roadways have been paved with stone in its various forms and shapes; wood, treated and untreated; rock and sheet-asphalt, bituminous macadam, bituminous concrete, cement-concrete, iron, brick, slag, india rubber, shells, earth, sand-clay, burnt clay, gravel and even glass, leather and hay. As a result of all this experimental work it is generally accepted that there are five standard pavements, namely, those formed of stone blocks, treated

wood blocks, brick, sheet-asphalt and bituminous concrete. Forty years ago not 1 mile of pavement existed in this country that would be considered standard in 1918.

The Value of Pavements to a city or any particular locality is positive and immediate. In actual money, the value of city pavements is very large. In New York City alone there were on January 1, 1915, 2 394 miles of pavement. Assuming the cost of a pavement to be $2.50 per sq yd and the average width of street to be 30 ft between curbs, the cost per mile, including the curbing, will be about $55 000, making a total of $131 670 000 that New York City would have invested in her streets if the pavement were of good character and in good condition. Or, assuming that each street must be repaved every 20 years, to keep the above mileage renewed when worn out would require the laying of 120 miles of pavement each year. Assuming further that the average cost of repairs to these pavements will be nothing for the first 5 years, and only 5 cents per sq yd for the remainder of their life, the total annual expense for the maintenance and repair of the 1915 mileage of New York City's pavements would be $880 per mile, or $1 580 480 for repairs and $4 224 000 for renewals, assuming renewals to cost $2 per sq yd, or a sum total of $5 805 480 per annum to keep the paved streets of New York City in good condition. As a matter of fact, according to the report of the Chief Engigineer of the Board of Estimate and Apportionment, New York City, in 1912 the city appropriated $14 600 000 for repairs, renewals and original pavements. Other cities will have smaller expenses than these, but this illustration shows the necessity for careful study and investigation. An inventory was made of the pavements in the City of New York in 1912. They were supposed at that time to be worth $58 000 000.

Real estate owners, than whom no more shrewd or sagacious men are in business, recognize the value of pavements, and, when they wish to put a piece of property on the market at once and at good prices, always pave the streets with the most popular material. The pavement improves the appearance of the streets so much that the lots not only sell more rapidly but the owner can add to his price more than enough to reimburse him for his outlay.

This was illustrated very forcibly in a section in Brooklyn, N. Y., where a large tract was put upon the market at one time, but first the streets were all improved and the subsurface work constructed, so that property owners not only knew the condition of the pavement in front of their own property but also in the entire section. This was a particularly successful enterprise. In the Borough of Manhattan, New York City, builders will not begin operations on an unpaved street, knowing the difficulty of making sales or obtaining desirable tenants unless the street is well paved.

Increase in Mileage and Change in Character of Pavements. Table I shows the total mileage and the mileage of the different kinds of pavements in use in the cities of Brooklyn, Boston, Buffalo, Chicago, New York, Philadelphia, St. Louis and Washington, D. C., in 1890 and also in 1915. Brooklyn is considered by itself, as it was a separate city in 1890, and New York represents only the Boroughs of Manhattan and The Bronx, as in 1890 they constituted one city. It will be noted that, not only has the amount of pavement increased from 3146 miles in 1890 to 6986 miles in 1915, but that the modern pavements, like sheet-asphalt, brick and wood block have increased much more rapidly. Creosoted wood block pavement, for instance, was not in use anywhere in 1890, and brick only in Boston, Buffalo and Philadelphia, and then to so small an extent as to be almost negligible. If the cities of the Central West were taken into consideration the increase in brick would be a much greater proportion. The increase

in sheet-asphalt shows its wonderful popularity, and it has come into almost general use as the most popular pavement.

Table I

	Brooklyn		Boston		Buffalo		Chicago	
	1890	1915	1891	1914	1890	1915	1890	1915
Sheet-asphalt	10.85	565.99	4.65	22.13	106.03	259.78	9.24	710.46

Totals: 1890, 3146.18; 1915, 6986.17

2. Principles Underlying the Selection of a Road or Pavement for a Specific Highway

In order that the highway official or legislative body ordering roads or pavements may do it intelligently, it is necessary that they should know, not only the properties of the different kinds of paving material, but also the requirements of the highways to be paved. This is not generally understood or recognized. If an architect, or an engineer in any other line

is about to make plans and specifications for a new structure, he first learns to what purpose the proposed structure is to be put, and then, and not till then, can he intelligently decide upon the proper materials for the different portions of the structure. This is just as important in a pavement as in any other structure, but not so easy to obtain. Different officials speak of different kinds of traffic as heavy, medium and light, but these terms have no positive or definite meaning. They are relative wholly, as what is heavy traffic for Rochester, N. Y., might be medium traffic for New York City, and at that the terms would be used only according to the individual judgment of the persons using them. Different schemes have been in use for determining the kind of traffic upon different streets. This is done by counting the number of vehicles passing a given point during a specified time and fixing a certain weight for the different vehicles, and in this way obtaining the supposed amount of tonnage passing over any street during this specified time. While this method is of some value, as giving approximately the wear on the pavement, it is not definite, as no rating is given to the conditions under which the tonnage is carried. It will be easily understood that two loads weighing 10 tons each will have a different effect upon a pavement than 20 tons carried over the same pavement in ten different vehicles. It will make a difference whether the vehicles are horse-drawn or motor-driven, whether the tires are of rubber or of steel, and whether of 1 or 4-in in width, and whether the vehicle is moving at a speed of 4 miles or 20 miles an hr. All these conditions must be taken into consideration in order to get a fair and comparable result of different tonnages borne over different pavements. It will be seen, therefore, that the problem is not a simple one, but one that requires much careful study. Only a few highway departments in the United States, and not many in foreign countries, have any census statistics of their highways that are of value, and, until they have such data, it is not possible to determine from a scientific standpoint the proper roads or pavements for different local conditions. See Sect. 4, TRAFFIC CONSIDERATIONS.

English Road Board Determinator. It would seem, however, that by proper experimenting a traffic unit could be arrived at and so standardized that a more definite result could be reached than is possible at the present time. The English Road Board has constructed a machine for experimental work to determine just what will be the wear on certain pavements by different weights moving on wheels at different rates of speed. The machine consists of an apparatus formed by spokes radiating from the center, on the under side of which, near the end, are attached wheels with proper contrivances so that different pressures can be exerted by springs corresponding to certain weights. These wheels are staggered on the spokes in such a way that in revolving they cover the roadway on which they run an even number of times. These wheels can be arranged with tires of any kind or of any width, with which it is desired to experiment, and the roadway paved with any material that is desired. By the arrangement of springs a given pressure can be obtained upon the wheels and the entire machine rotated at an even speed, so that with a certain number of revolutions the amount of wear on the pavement can be observed. This arrangement probably conforms more closely to actual wear on the street than any other that has yet been devised. Of course, the action of horses' hoofs cannot be determined. It would seem that, by a sufficient amount of experimenting with a machine of this character, a traffic unit could be evolved, to which different kinds of traffic could be referred, so that if the traffic on any street in any city could be said to be a certain number of traffic units per yard of roadway per day it would be known quite definitely what was meant. For instance, if it was discovered that the passing of wheels under a given load with 2-in tires, at a certain speed and with a certain weight per inch of tire, would wear a standard pavement a certain amount, that amount of traffic could be taken as 100 traffic units. Then the amount of wear with different loads, at different speeds

and with different tires, necessary to produce the same amount of wear could be referred to the same standard and its value in traffic units be determined by reference to the original standard. But even if this could be determined positively there would still be the difficulty of determining the exact amount of traffic on any street, but with experienced observers the results would be fairly accurate. It would seem that before traffic conditions can be figured accurately and scientifically some such scheme as the foregoing must be used.

Number of Vehicles on European City Streets. A knowledge of the number of vehicles using streets in different cities is of value. It is stated in the report of the Chief Engineer of Paris that on the Rue de Rivoli 42 035 vehicles passed in 24 hr. The following statement shows the daily traffic on some of the principal streets of foreign cities: Paris, Rue de Rivoli, 42 035, Avenue de l'Opera, 29 500, Rue Croix des Petit Champs, 20 480, Rue St. Honoré, 19 672; London, King William St., 26 [illegible]; Gracechurch St., 15 585, Queen Victoria St., 16 531, Cheapside, 15 206; Sydney, Australia, George St., 11 960.

Number of Vehicles on City Streets in the United States. In 1885 a series of observations were made under the direction of Gen. F. V. Greene to determine the amount of traffic in several American cities. The figures represent the number of vehicles of all kinds passing between 7 A.M. and 7 P.M.: Broadway, New York City, [illegible]; Broad St., Philadelphia, 6081; Devonshire St., Boston, 5362; Douglass St., Omaha, 4752; 15th St., opposite Treasury, Washington, D. C., 4520; Clark St., Chicago, 4389. In 1914 observations in the Borough of Brooklyn, New York City, showed the greatest number of vehicles in 8 hr to be 2815, on Flushing Ave. The traffic on this street, however, is made up of heavy units, as it is a street where there is a great deal of trucking. Observations taken in the Borough of Manhattan, New York, in 1914, show that on Fifth Ave., between 33rd and 34th Sts., 7520 vehicles passed between 8 A.M. and 6 P.M., and between 41st and 42nd Sts., 6803 vehicles. It might be of interest to know that only 15% of this total number of vehicles was horse-drawn between 33rd and 34th Sts., and 16% between 41st and 42nd Sts.

It may seem strange that the traffic in New York should be so much less in amount than that of Paris or London, but it must be remembered that the New York City figures are given only between 8 A.M. and 6 P.M. If these figures were continued on Broadway, for instance, from 6 P.M. to 12 midnight, they would undoubtedly be very much increased, if not doubled, as the automobile traffic between 42nd and 49th Sts. is without doubt greater during that time than at any other time of the day.

Requirements of Pavements. After a highway official ascertains the requirements of a highway, in order to fulfill those requirements fully, the properties of the different materials to be used in paving must be understood thoroly; and after that is known, and when it is practicable from a scientific standpoint, to determine the proper material, it will be found even then that common sense and good judgment must be used to a great extent, as many conditions must be taken into consideration. It will be found also that the wishes of the people doing business or living on the highway will not always coincide with the wishes of travel on the roadway, whether it be heavy business traffic, or light automobile traffic. The property owner wishes a quiet, smooth pavement, and one that is pleasing in appearance; the automobile owner wishes one that is smooth, and the truckman, one that will be durable, present light resistance to drawing a load, and give a good foothold for his horses, with no regard for noise; so that all the different property interests must be taken into consideration in addition to the scientific requirements and needs of the street. But the highway official must make a study of the different characteristics of the paving materials in order to have an intelligent idea as to how they should be used. The official, who decides on the material after the most careful investigation, will often find that the decision is displeasing to many people. This often must be the case, as the wishes of the users of a street many times conflict with the wishes of the people who do business on a street.

The users of a street desire a pavement that is most conducive to ease of trucking, and, if that be satisfactory, care little for the noise or other inconvenience, while the people who do business on a street, or occupy residences thereon, wish a quiet pavement and are not so much interested in its adaptability to traffic. The decision must be made after taking all things into consideration and adhered to, altho it will not always prove satisfactory to all. The appropriation is generally inadequate for the work, and careful study is necessary to bring about the best results. An eminent authority has said that if one has but 5 min in which to perform a difficult task, 3 min should be consumed in ascertaining how to do it.

3. Characteristics of an Ideal Road or Pavement

While no road or pavement that has ever been laid is perfect, in considering the subject it is necessary to take a perfect road or pavement as a standard. Such a road or pavement should be cheap, durable, easily cleaned, present light resistance to traffic, be not slippery, be easily maintained, be favorable to travel, and sanitary. Admitting that a perfect road or pavement should have these properties, it must be understood that they are not all of the same importance; but by discussing these different properties, and assuming that a perfect road or pavement has a value of 100, it will be possible to assign a percentage value to each one of these properties, and then, by referring these values to the different kinds of paving material, determine a percentage value for each type.

Cheapness. It may be said that cheapness is not a physical characteristic of any material. This is undoubtedly true. It must be admitted that it is an important factor. No matter how desirable, or how economical ultimately, any material may be, its first cost is a question of importance in deciding upon its availability. If a property owner or a highway department cannot pay for it, the question is settled at once; there is no chance for argument. A recommendation is often rejected, when its wisdom is not questioned, simply on account of the cost. When the best cannot be taken this phase is developed: with the money available, how can the best results be obtained? A person presenting a new plan or a new material will first be asked as to its cost, and, if it be expensive, it will be a hard task to have it receive a fair trial, except at the expense of the party commercially interested. Cheapness depends to a great extent upon locality. Thus a cheap material in one locality might not be a cheap material in another. For instance, paving brick is manufactured to a great extent in the Central West and can be furnished to nearby cities at a reasonable price, while the same material in New York or New England might cost so much, on account of the freight rates, as to be prohibitive. At the same time granite blocks, which can be cheaply supplied to all cities on the coast, would be expensive in the interior cities. Asphalt, on the other hand, forming so small a proportion of the weight of the entire pavement, is not affected to so great an extent by cost of transportation. So that, while cheapness as a property may have a certain value, the different materials will vary greatly in this respect. Cheapness, therefore, has been given a value of 15.

Durability. This is also an economic property. Upon this depends ultimate cost, and in this connection must be considered to a certain extent first with cost. If a pavement be cheap, and pleasing even, it can never be a complete success if it has not durability. Americans expect any construction to care for itself largely; they are not given to economies in repairs. Durability is affected by so many varied conditions that it

is discussed with difficulty. Paving materials have a physical life as well as a traffic life; that is, stone and brick are not affected by the action of the atmosphere and will last in a roadway until they are worn out by the traffic. Asphalt and untreated wood, however, have a limited life, even without traffic; in fact, it is probable that the life of both of these materials in a pavement is increased by a certain amount of traffic. The influence of traffic is modified by five principal conditions, namely, width of roadway, character of road or pavement, presence or absence of street-car tracks, state of repairs, and how well the pavement is cleaned.

Width of Roadway. The distance between curbs or shoulders affects traffic, as it tends to scatter or congest it. The wider a roadway is, the more even will be its wear. If several lines of traffic can be maintained irregularly over the surface of the roadway, the wear will be more uniform and a better service received from the road or pavement. When vehicles are restricted to direct lines, the wheels move in practically the same place from day to day, and the result is a rough and uneven surface in a comparatively short space of time. Then, too, there is a certain part of the roadway adjacent to the curb or car track that cannot be efficiently used. This width is positive, and, in a narrow roadway, proportionately reduces the available roadway for traffic much more than in a wide roadway. If, for instance, this unavailable space is 2 ft on each side, on a 30-ft roadway there would be left 26 ft for traffic, while on a 60-ft roadway there would be 56 ft left for traffic; so that, while the actual roadway would be doubled, the available roadway for traffic would be more than doubled.

Character of the Road or Pavement. By this is meant, not the material that is used, but the detailed method adopted in constructing the roadway. Sheet-asphalt pavements, for instance, have been standardized, slight variations being made sometimes to meet special traffic conditions, but with stone, brick and wood it is different. While concrete as a rule is used for foundations for these different materials, it is not always so used. The joint filling varies according to the experience or the inclination of the particular engineer in charge. Wood of one variety is used in one locality and of a different kind in another, and while at present it is treated chemically in nearly all cities, the material used and the amount of the preservative are generally different. So that wood, stone, or brick, as referred to pavements, are somewhat indefinite unless it is known just how they have been used.

Presence or Absence of Street-Car Tracks. All foreign constructions in the surface of a roadway have a very material influence on its wear. Manhole heads are of iron, and must necessarily be of a different degree of hardness from the road or pavement, no matter what its character. As it is impossible to keep the surface of the roadway always level with the manhole head, when the wheel leaves the iron it pounds upon the roadway with greater severity, inducing greater wear than would occur if the surface were smooth and even. While manhole heads are objectionable, they are not as great a detriment to the pavement as the car tracks. It is recognised by all engineers that car tracks must exist in city streets, but it is also recognized that they cause extra wear of the pavement. This is not only because it is difficult to keep the tracks at the same level with the pavement, but because if the tracks are in fairly constant use, the traffic is concentrated on the sides of the streets and in practically regular lines. With a sheet pavement like asphalt the horses' shoes, especially in warm weather, often mark the pavement very materially. If the street is free

from car tracks the wheels of the different vehicles are likely to iron and smooth out the inequalities caused by the horses' shoes, which cannot often be done on car-track streets, because the traffic is restricted to distinct lines. In 1911 it cost 6.5 cents per sq yd to keep in repair the sheet-asphalt pavement on street-car streets in the Borough of Brooklyn, New York City, and 2.9 cents per sq yd on streets where there were no car tracks. In 1914 it cost 3.4 cents per sq yd on street-car streets, and 1.9 cents per sq yd on streets where there were no tracks. In a report of the Department of Public Works of Buffalo for 1910, it is stated that the presence of street-car tracks in streets reduces the life of the pavement about 2 years.

State of Repair. This is of vital importance in the maintenance of roadways. The old saying, " A stitch in time saves nine," can be applied with as much force to roads and pavements as to any other form of construction. If holes, depressions, ruts or any other defect in the surface are allowed to remain for any length of time, the material is displaced and consequently is worn abnormally. It is possible to permit a street to get into such condition that traffic will avoid it, so that it will not be worn extensively, but all streets should be kept in as nearly perfect condition as possible at all times, and in any discussion of this character the assumption is made that such is done. This fact impresses itself if the action of traffic upon stone blocks that have been relaid temporarily in a trench awaiting final reconstruction is observed. The unevenness of the surface and the looseness of the blocks allow the corners to be worn off and the blocks damaged very much more than if the pavement were smooth and even. It is very noticeable in any large city that the pavement in front of a park and large public buildings, where the surface is not disturbed for any subsurface work, is always more durable and in better condition than where it is regularly built up on both sides. No matter how well the pavement may be replaced temporarily, there is always an undue amount of wear upon the edges of the excavations. It often happens that in large cities in the construction of business blocks the basement excavation is carried out to the curb line, which always causes a settlement in the pavement proper; and when building material is stored on the street, the traffic is diverted to one side, causing an undue wear, especially if the pavement be sheet-asphalt. While it is difficult to figure upon the exact effect of the openings in pavements, as it depends so much upon the number of openings and the character of the traffic, it is probably true that if no openings of any kind were made in a pavement its life would be increased 15 to 20%.

Cleanliness. The effect of refuse on a roadway varies with its character. Any imperishable material is benefited by having a cushion of detritus upon it; it serves as a carpet to protect the road or pavement, which, when the cushion is heavy enough, becomes really the foundation. This fact will often explain why certain materials are much more durable in a small city than in a large one. A poor brick pavement, for instance, will often give good results in a small place, where the pavements are cleaned only at long intervals, when it would rapidly fail if kept clean under the same traffic. This, however, will not hold good with wood or sheet-asphalt pavements. Any street debris collects and retains moisture, which hastens the action of disintegration and decay in any perishable material. A case was cited where the contractor refused to repair a sheet-asphalt pavement, where the guarantee required that the pavement should be kept in repair from the effects of traffic, because the pavement was not kept normally clean, and for that reason it wore much more rapidly than it would normally,

and that the guarantee could not, therefore, be enforced. While this point was argued to a considerable extent, the court decided that the contract required repairs to be made when ordered by the City Engineer, and that the question of proper cleaning was not material.

All of the conditions referred to modify the action of traffic, and thus affect the durability of any material. Durability has been considered to have a value of 21.

Easiness of Cleaning. The experience of the larger cities, and in more recent years of all cities that have pavements, has demonstrated that it is not only feasible but extremely desirable to have pavements kept free from natural street refuse. In fact, it is generally accepted that it is not only desirable but absolutely necessary, and, while all cities recognized this, the degree of cleanliness must be governed by the amount of the appropriation. The appropriation for the Street Cleaning Dept., New York City, for 1915, was $7 646 186.74. The benefit of smooth pavements as related to street cleaning will be appreciated from a statement made by Waring (29), at a meeting of the Am. Soc. C. E., who said that if all the streets of New York, meaning at that time Manhattan and The Bronx, were paved with sheet-asphalt, where the grades would permit, and the street-car tracks constructed with grooved rails, the cost of sweeping the entire city would be reduced from $1 200 000 per annum to $700 000 per annum; that is, there would be a saving annually of $500 000 in New York, which then had a pavement mileage of 431, of which 95 miles only were paved with sheet-asphalt. While this statement was made in 1896, the principle is as good to-day as then, and is one of the very few statements that can be quoted definitely on this subject. A value of 15 is given to easiness of cleaning.

Resistance to Traffic. This is a very important item. One of the chief provinces of a road or pavement is to reduce resistance to traffic, and consequently any road or pavement that can bring it to a minimum is of special value. Any mechanical device that would reduce the friction of a machine 25 or 50% would be recognized at once as of great benefit. There is more than this difference in various roads and pavements, and this difference must be fully considered and carefully weighed before deciding on any particular material. If one horse can draw on one road or pavement a load that would require two horses on another, the truckman at once sees the importance of a proper selection. Of course, all highways are not heavy traffic streets, but the application in this respect will be taken up in detail later. Light resistance to traffic is valued at 15.

Non-Slipperiness. The slipperiness of a pavement depends upon its material, also upon its condition and how constructed. The efficiency of a draft horse varies with foothold. If that be good, the entire strength of the horse can be used to draw the load; while if there be constant danger of slipping and falling, very little will be accomplished. Instead of using all power to overcome the resistance of the load it is used only to the slipping point, and often a horse has difficulty in maintaining a foothold even if there is no load to draw. The condition of the weather and the climate modifies this. An illustration of this was shown in a case where observations were being taken on several sheet-asphalt paved streets in extreme winter weather. On the first day the hourly traffic was 225 tons between 11 and 12 o'clock, reaching 270 tons between 3 and 4 P. M. On the following day the traffic between 11 and 12 o'clock was 305 tons. About 2 P. M. snow began to fall, the mercury being about −18° C (0° F), making the pavement so slippery that the traffic was reduced to 40 tons between

3 and 4 P. M., and the street was soon practically deserted. The same results were obtained on all other streets where observations were being taken. Non-slipperiness is assigned a value of 7. In the light of the foregoing statement this value may seem small, but it must be remembered that these special conditions seldom arise, and, altho effective while they exist, do not have as much influence as a smaller force acting continually. For instance, if a street is used by a continuous traffic, without regard to weather, slipperiness is extremely important, but then only on the days when weather conditions materially affect the surface. If, on the other hand, the street is in such a locality that the traffic can be easily diverted on days when the pavement is especially slippery, the slippery quality is not of such great importance.

Ease of Maintenance. Maintenance is closely allied to first cost, and many engineers think that they should be taken together. To a certain extent this is true, but mainly when the question of ultimate economy is being considered. The cost of repairs should be ascertained as accurately as possible in advance. No material can be intelligently adopted without it. What often seems a wise and sound selection is ruled out simply by the cost of repairs. All works constructed by man require constant attention, and a pavement is no exception to the general rule; but that material which needs the least, and allows that to be done at the least expense as well as convenience to the public, is the best, other things being equal. By ease of maintenance is meant, not simply the cost, but whether the material is of such a character that repairs for pavement openings of whatever kind can be easily made and the original condition approximated. It is probably absolutely impossible to replace a pavement over a cut in general practice so that it will be as good as before it was opened, but it can be more nearly approached with some materials than with others; and as it must be recognized that openings will be made in pavements despite all precautions, the material that can be easily and properly replaced has a distinct advantage. This property is given a value of 10.

Favorableness to Travel. By this is meant the ease and comfort that are enjoyed in driving over a smooth pavement, and also the decrease in the wear and tear of vehicles as compared with one that is rough and uneven. It is difficult to estimate this exactly, but some approximations have been made.

French engineers make the general statement that 50% is saved in the wear and tear of vehicles by having smooth pavements. A London engineer in 1827 stated that good pavements in London, Westminster and Southwark would save £140 000 ($681 000) per annum in wear and tear of vehicles and horses. The area included in the above was 3818 acres. It must be remembered, however, that the streets of London at that time were in especially bad condition. In 1871, Deacon (14) stated that since the new Liverpool pavements had been constructed, without giving credit for the great reduction of wear and tear of horses and vehicles, there was a saving of £10 000 ($48 700) per year for every mile of the new pavements now laid on the dock line of the streets of Liverpool.

Smooth pavements are a luxury also. It is a pleasure to drive on some streets and positively painful on others. Wheeled vehicles are equipped with pneumatic tires to make the pleasure as great as possible, but much can be done to aid it in the pavement itself. With the introduction of the automobile and the motor-truck, with their rubber tires, and the possibility of their extension, this property of favorableness to travel is bound to receive more attention. At the present time, 1918, it is valued at 5.

Sanitariness. Another important requisite of a road or pavement is

that it should be sanitary. A great amount of decaying organic matter, house garbage, horse-droppings, and various kinds of filth must be deposited in the highways despite the utmost care. Altho the great introduction of automobiles, both for pleasure and business, has reduced this amount very materially, the matter still is of great importance. Any road or pavement that will allow any of this filth to collect in joints or soak down to the surface of the underlying soil or foundation, must be deleterious to the public health. Any material that will readily absorb moisture and give it forth in dry seasons must be considered as unsanitary. This fact is generally understood by municipal engineers, and it is recognized that all pavements should be practically waterproof. Therefore a road or pavement with a smooth surface impervious to water and not made up of organic matter subject to decay will be desirable from the standpoint of the sanitarian. Noise, too, is an important factor. A noisy material prevents sleep, rasps on the nerves of both the sick and the well. This fact is considered of great importance in large cities, where in selecting a material for repaving any street special care is taken that noiseless pavements be laid in front of churches, schools and hospitals. This is recognised to such an extent that noiseless pavements are laid on many streets despite the fact that it is understood that it is not proper from an economic standpoint. In the great improvement that has taken place in sanitary conditions in cities since 1890 the improvement in the character of pavements has been an important factor. Sanitariness is rated at 13.

4. History Cards and Report Forms

History Cards often supply the most valuable data that can be obtained in connection with the selection and design of highways. They correlate actual results of the use of methods and materials under known conditions Such results are of inestimable value in the preliminary investigations of other highways and the comparison of the relative suitability of the various types of roads and pavements for given local conditions.

History Cards Recommended for the Use of the N. Y. Highway Comm. (9). There are submitted herewith forms embodying outlines of the data which history cards should contain. "Form No. 1 should be considered as the main history form, printed upon 5 by 8 in white cardboard. Upon the back of this card the maintenance and repair record, shown on form No. 2, should be printed. A material record card, shown in form No. 3, printed upon light green cardboard; a traffic record card, shown by form No. 4, printed upon light pink card board; and a history of physical condition record, shown by form No. 5, printed upon light buff cardboard, should accompany each history card. Under ordinary conditions the four cards, when filled out, will constitute the complete history of a given highway.

"Material record form No. 3 should be of great assistance in correlating service results with the actual quality of the materials of construction; and while the card itself does not contain a complete record of tests, all of the information necessary to quickly secure such records is given. The last column headed Physical Characteristics would contain the results of some of the most important physical tests such as abrasion and absorption for brick, loss on abrasion and toughness for stone, penetration for asphalt, etc.

"Traffic record form No. 4 and the tally form are of course two distinct records, the former being a summary of a number of the latter.

"History of physical condition, form No. 5, should constitute a dated record which would cover such information as disintegration, nature and probable cause, displacement of surface, ruts, potholes, waves, etc; condition in summer, soft or otherwise; condition in winter or when wet, slippery or otherwise; nature of wear, condition adjacent to curbs, edgings, shoulders and rails; wear on curves and steep grades; and effect of various classes of traffic.

Form No. 1.—General Data and Original Construction.

Highway No............... Type...
Specifications, year............ Title, Type No. or Item No.......................

NOTE. This form should be printed on front and back of light pink cardboard.

Form No. 5.—History of Physical Condition of Highway

Highway No..............

Date	General Description

NOTE. This form should be printed on front and back of light buff cardboard.

Records of Cost Data are essential if an intelligent comparison is to be made of the relative value of different types of roads and pavements.

Lewis (21) states that "Cost records of highway work should indicate as clearly as possible the proportion of the expense chargeable to:

1. Permanent betterments, such as land purchases, grading, the improvement of lines and grades, masonry and steel bridges and culverts. This part of the work once done may be considered permanent or sufficiently durable to outlast more than a single generation.

2. Curbing, gutter pavement, fencing, guard rails, wooden bridges, concrete foundation, planting, etc, all of which may need periodical repairs, but will probably last 20 years at least.

3. The roadway surface, which will begin to deteriorate at once, and will need constant attention and periodical renewal.

"For each piece of work the records should include:

1. The character and first cost of the materials.

2. Cost of delivery on the work, with kind of transportation and distance hauled.

3. Cost of labor of all classes and the quality of same.
4. Cost of present value of plant and equipment, with allowance for depreciation due to the work under construction and not previously marked off.
5. All overhead charges, including engineering and inspection.
6. Cost of bonds, permits, etc.
7. All delays due to weather, failure to receive materials, strikes, or other causes.
8. A precise description of the methods employed and of the surface treatment of the road.
9. A statement as to the results obtained, the probable causes of failures or unsatisfactory work, and the means employed to correct or remedy them.
10. The manner in which the funds to pay for the work are raised, whether by cash appropriations, by the issue of bonds, with length of term and rate of interest, or by money advanced in anticipation of the collection of assessments for benefit."

Form of Record for Data Concerning the Use of Highway Materials, as recommended by the Spec. Com. Mat. Road Cons., Am. Soc. C. E., in its 1918 Rep. (6c). " The following forms of records are recommended for the use of Highway Engineers. They cover both bituminous and non-bituminous materials. Altho combined in a single table, it is believed that the data for different kinds of road surfaces can advantageously be placed on separate sheets or cards for convenient filing and reference."

Non-Bituminous Materials

The following data or such parts as apply to a particular road or street could be incorporated on the sheet or card containing the data immediately preceding, or could be placed on a separate sheet or card containing the results of tests and analyses.

BROKEN STONE AND BROKEN SLAG. Name and origin; specific gravity; absorption of water per cubic foot; abrasion, percentage of loss; toughness; cementation; crushing strength per square inch; mechanical analysis; percentage of voids, loose and compacted.

GRAVEL. Location; specific gravity; abrasion, percentage of loss; cementation; mechanical analysis; percentage of voids, loose and compacted.

SAND. Location; specific gravity; mechanical analysis; percentage of voids, loose and compacted; tensile strength in cement briquettes, as compared with standard Ottawa sand.

MIXTURES OF SAND OR OTHER FINE HIGHWAY MATERIALS WITH BROKEN STONE, BROKEN SLAG, OR GRAVEL. Specific gravity; mechanical analysis; percentage of voids, loose and compacted.

PAVING BRICK. Composition; name of manufacturer; rattler test, percentage of loss.

STONE BLOCK. Name and origin; specific gravity; absorption of water per cubic foot; abrasion, percentage of loss; toughness; hardness; crushing strength per square inch.

WOOD BLOCK. Character of wood; weight of blocks; soundness; rings per radial inch; quantity of preservative; absorption of water after treatment. Character of preservative: Specific gravity at 25° C (77° F); specific gravity at 38° C (100° F); solubility in benzol or chloroform; water content. Distillation of preservative: Up to 170° C; 170° to 200° C; 200° to 210° C; 210° to 235° C; 235 ° to 270° C; 270° to 300° C; 300° to 315° C; 315° to 355° C.

PORTLAND CEMENT. Loss on ignition, percentage; insoluble residue, percentage; specific gravity, retained on 200-mesh sieve, percentage; retained on 100-mesh sieve, percentage; steam test; initial set, time in minutes; final set, time in minutes; tensile strength, neat, 24 hr; tensile strength, neat, 7 days; tensile strength, 1:3 Ottawa sand, 7 days; tensile strength, 1:3 Ottawa sand, 28 days; compressive strength, per square inch; constancy of volume.

Mechanical Analysis	Percentages by Weight

Bituminous Materials

The following forms are given as illustrations of those to be used for recording the properties of bituminous materials.

Asphalt Cements for bituminous Macadam, Bituminous Concrete, Asphalt Block and Sheet-Asphalt Pavements and Fillers for Brick and Stone Block Pavements. Trade name; manufacturer; general characteristics; specific gravity at 25° C (77° F); flash point. Solubility in CS_2, carbon disulphide: Organic matter insoluble; inorganic matter insoluble. Solubility of bitumen in CCl_4, carbon tetrachloride; solubility of bitumen in petroleum naphtha; penetration 4° C (39° F), 200 g, 1 min; penetration 25° C (77° F) 100 g, 5 sec; penetration 46° C (115° F), 50 g, 5 sec; float test; melting point by ring and ball method; ductility at 4° C (39° F); ductility at 25° C (77° F); fixed carbon content; paraffine content. Loss on evaporation at 163° C (325° F), 5 hr; penetration of residue 4° C (39° F), 200 g, 1 min; penetration of residue 25° C (77° F), 100 g, 5 sec; penetration of residue 46° C (115° F), 50 g, 5 sec; melting point of residue by ring and ball method; float test on residue; ductility of residue at 4° C (39° F); ductility of residue at 25° C (77° F).

Tar Cements for Bituminous Macadam and Bituminous Concrete Pavements and Fillers for Brick and Stone Block Pavements. Trade name; manufacturer; general characteristics; water; specific gravity at 25° C (77° F); flash point; solubility in CS_2, carbon disulphide; specific viscosity, Engler; melting point, by cube method; float test. Distillation by weight and by volume: Up to 110° C; 110° to 170° C; 170° to 235° C; 235° to 270° C; 270° to 300° C; specific gravity of total distillate at 25° C (77° F); melting point of residue, by cube method; float test on residue.

PROPERTIES OF PAVEMENTS

5. First Cost of Pavements

The pavements that will be considered, for illustrative purposes, are the regular oblong granite blocks, with bituminous and gravel, and cement-grouted joints; sheet-asphalt, with a wearing surface 2 in thick and binder 1 in thick; vitrified brick, the joints being filled with bituminous material or Portland cement grout; treated wood blocks, and Bitulithic, all laid on 6 in of Portland cement-concrete. The discussion is too general to take up in detail the different methods of laying the various kinds of pavement, altho of course in actual wear that would be very material.

The first cost of pavements will vary very materially in every locality and a different apportionment must accordingly be made for every change in price. The cost will vary, too, in addition to this, in accordance with

general conditions as well as competition or variation in price of the materials. The following figures are based upon what would be considered average prices per sq yd in New York City under ordinary conditions, altho they are somewhat higher than bids received in 1915: Granite block, $3.50; wood block, $3.50; sheet-asphalt, $2.00; brick, $2.25; Bitulithic, $2.35. Note: The price of the brick and the Bitulithic is estimated, as neither of these materials is laid to any extent in New York City.

Bituminous Pavements. Blanchard (8), gives the average cost of constructing a bituminous surface, using ½ gal per sq yd with either an asphaltic or a tar product, or a combination of the two, as 7 cents per sq yd, but that the cost of bituminous concrete pavements varies with the kind and quantity of bituminous material used, the character of the aggregate, and the type of construction employed. As an illustration of that he gives the cost of one type, which he describes in detail, as being from 25 to 35 cents in excess of water-bound macadam, and for two other types, with mineral aggregates of broken stone and sand, with or without other fine material, at $1 to $2.25 per sq yd, including the foundation course and light grading.

Crosby (8) states that the cost of building a bituminous macadam pavement, using 1¼ to 2¼ gal of bituminous material per sq yd, averages between 15 and 25 cents per sq yd over and above the cost of water-bound macadam under the same conditions.

There are a great many different kinds of bituminous pavements and the costs vary very materially. On a large contract for a bituminous concrete pavement constructed around the Ashokan Reservoir in New York State, where the road crust was formed of stone passing over a ½ in screen and thru a 1½ in screen, the stone being properly heated, and mixed with an asphaltic cement so that the resulting mixture contained between 5 and 7½% of bitumen, the surface after rolling being covered with a seal coat of hot asphaltic cement at the rate of a little less than 1 gal per sq yd, the cost was $1.01 per sq yd for a surface 2 in thick.

In the Borough of Queens, New York City, 100 miles of roads were surfaced with a bituminous concrete pavement, known in that locality as the Topeka mixture, the mineral aggregate ranging from less than 10% passing a 2-mesh sieve to from 5 to 11% passing a 200-mesh sieve, the finished pavement containing between 7 and 11% of bitumen, and costing from $1 to $1.25 per sq yd for 2 in of thickness. In 1914 roads of this character were laid in New York State by the State Highway Department at a cost of 85 to 95 cents per sq yd.

In New York State in 1914 bituminous macadam pavements 3 in thick constructed by the penetration method were laid at a cost of 50 to 60 cents per sq yd. Breed (10) states that in 1916 the average cost of water-bound macadam, on 434 highways, was $0.648 per sq yd; and of bituminous macadam, on 134 highways, was $0.871.

In Massachusetts, in 1914, using 2¼ gal per sq yd of Bermudez asphalt, the cost of bituminous macadam was from 65 to 80 cents per sq yd for a 2-in thickness. A road crust composed of oil asphalt and gravel, using 18 gal of asphalt to 1 cu yd of gravel and spreading so as to have a thickness of 2 in after rolling, was laid at a cost of 30 to 35 cents per sq yd; while with oil asphalt and sand, mixed and spread to a depth of 4 in after rolling, the cost was from 54 to 60 cents per sq yd. Using the penetration method, with tar instead of asphalt, and with 2¼ gal per sq yd of surface, 2 in thick after rolling, the cost was 45 to 65 cents per sq yd. In explanation of these variations of cost it can be said that gravel cost 80 cents per cu yd and trap rock $2.50 per ton.

Cement-Concrete Pavements. When the traffic of a road is so heavy that a bituminous concrete crust does not seem to be proper, recourse is had to more durable materials, and asphalt blocks, brick, and even granite block are used. It sometimes occurs too that, even if under ordinary conditions a bituminous concrete would be suitable, the local conditions are such that Portland cement-concrete or brick will be more economical in the long run. Portland cement-concrete has come into very general use since 1910, and is now used to a large extent in all states where good roads are being built. While their first cost is somewhat greater than for some types of bituminous road crusts, their durability makes cement-concrete pavements an economical material, when ultimate cost is considered. The first cost varies a good deal in different localities.

In Wayne County, Mich., where cement-concrete pavements first received general recognition and where they are being used almost entirely in road construction, all materials have to be brought from out of the county, even the water with which the concrete is mixed is piped long distances, so that the cost is necessarily great. These roads cost on an average about $1.35 per sq yd. On Michigan Ave., where the concrete was laid an average depth of 7 in and mixed in the proportion of 1 part of cement to 1½ parts of sand and 3 parts of gravel, the cost was $1.47 per sq yd.

In Massachusetts cement-concrete roads laid in 1914, with an average depth of 7¼ in, cost from $1.40 to $1.55 per sq yd; while in New York State, in the same year, with a mixture of 1 part of cement to 1½ parts of sand and 3 parts of broken stone, the cost was $1 per sq yd, for a depth of 6 in. Breed (10) states that, in 1916, the average cost, on 20 highways, was $1.121 per sq yd.

Brick Pavements. Vitrified brick has been used extensively in the Central West, particularly in localities where it is manufactured and especially in the vicinity of Cleveland. Brick roads vary in cost according to the transportation charges, as the brick is exceedingly heavy, and freight charges make a material charge against the cost of the road. In the vicinity of Cleveland the cost has been from $1 to $1.10 per sq yd, not including foundation.

Conclusion. Assigning, then, values to these different materials inversely as the cost, granite block has a value of 2, wood block 4, sheet-asphalt 4, brick 3, and Bitulithic 3. These values are local and must be changed for each city.

6. Cost of Maintenance of Pavements

The cost of repairs to pavements varies greatly in different cities. It is governed principally by the character of the material, nature and amount of traffic, and the condition in which the streets are kept. In America very few satisfactory records are available on this subject. Few cities keep their accounts in such a manner that it is possible to tell how much money has been spent on different pavements. Then, too, officials of different cities have different standards of repair. One city will not tolerate what is considered good in another. Then some cities have only a certain amount of money and the figures given would show that sum rather than what was necessary to keep the pavements in repair.

Stone Block Pavements. ENGLAND. Brodie, City Engineer of Liverpool, estimates that 6-in stone blocks will sustain a traffic of 9 482 000 tons per yard of width before being worn out, and that the life of the pavement will be governed by the amount of traffic each year.

The stone block pavements of PARIS in 1911 cost 13 cents per sq yd.

Wood Block Pavements. Wood (4) gives the cost of repairs to wood block pavement as 2 cents per sq yd. This, however, is very much less than the cost in London proper, where it is given as 20 cents per sq yd on the average, altho some streets cost as high as 43 cents.

In LEIPSIC, GERMANY, the cost of keeping the wood block pavements in repair for 15 years after a guarantee period of 5 years was 5 cents per sq yd for hard wood block and 10 cents for soft wood blocks.

In PARIS, in 1911, the repairs to wood block pavements cost 26 cents per sq yd.

In VIENNA the cost of repairs to soft wood block pavements is given as 11 cents per sq yd.

UNITED STATES. In America, treated wood block pavements have not been laid long enough to get information as to the cost of repairs, but in 1912, from reports of the principal cities using wood blocks to any great extent in this country, it was found that at that time almost nothing had been expended for repairs due to actual wear and tear of pavement. For instance, the first creosoted wood block pavement, on Tremont St., Boston, had been in use, 1912, 12 years and had cost nothing for repairs, and it was stated by the engineer of the Boston pavements that the same was true of 14 000 sq yd of other wood block pavement laid about the same time. Pavements

laid in Brooklyn, N. Y., the oldest of which at that time had been in use 10 years, had cost on an average 0.05 cent per sq yd per year, altho it was stated by the engineer in charge that practically all of these repairs were due to causes other than wear and tear. In Brooklyn in 1914 the cost of repairs due to wear and tear only on 67 169 sq yd of wood block pavement was 0.7 cent per sq yd. In the Borough of Manhattan, New York City, there were three streets in 1912 that had been out of guarantee 3 years, having been kept in repair 5 years without cost to the city. One of these streets was of heavy, one of medium, and one of light traffic. The heavy traffic street had cost 7 cents per sq yd per year, and the average of all had been 6 cents per sq yd per year; but the cost of repairs due to wear and tear was on the heavy traffic street only, which is a wholesale street in the business section. Minneapolis, Minn., reported that on 1 000 000 sq yd of wood block pavements, all laid by the city and the first in 1902, the greater part of the material being Norway pine and tamarack, the cost in 1911 was less than 0.1 cent per sq yd. In St. Louis, in 1909, repairs to 50 000 sq yd of wood block pavement, laid in 1903, cost $2.10, and in 1911 the same 50 000 sq yd cost less than 0.2 cent per sq yd, so that the total cost of repairing the 50 000 sq yd of wood block pavement the first 9 years they were laid was 0.2 cent per sq yd. These pavements were all on light traffic streets.

Rock Asphalt Pavements. LONDON. The average cost of keeping in repair the rock asphalt pavements of London is 30 cents per sq yd per year, but one contract was made for repairing the rock asphalt pavement on Cheapside for 15 years, after it had been laid 2 years, at a price of 56 cents per sq yd per year.

In GLASGOW, Scotland, the cost of repairing rock asphalt pavements ranges from 8 to 20 cents per sq yd per year.

In PARIS in 1911, the cost of repairing rock asphalt pavements was 19.5 cents per sq yd.

Sheet-Asphalt Pavements. UNITED STATES. In Brooklyn, N. Y., in 1914, the cost on 5 875 000 sq yd was 2 cents per sq yd, but 0.4 cent of this was due to causes other than wear and tear. On railroad streets the cost was 3.4 cents and on streets, where there were no tracks, 1.9 cents per sq yd. In Buffalo, the cost of repairs in 1913 for sheet-asphalt was 3.17 cents per sq yd, but in a series of years the cost had been 3.78 cents for 43 000 000 sq yd.

Bituminous Macadam and Bituminous Concrete Pavements. In Massachusetts in 1914 the cost of repairs to 450 000 sq yd of bituminous macadam, heavy hot oil being used in the construction, the work having been done between 1911 and 1914, was $0.0119 per sq yd. The lowest cost on any one of these roads was $0.0043 per sq yd, on a road where the traffic consisted of about 200 automobiles and 75 vehicles with steel tires per day. The highest cost was $0.0234 per sq yd, on a road where the average traffic was about the same as on the above, but the material used was not supposed to be of so good a quality. On the same kind of a road, but where asphalt was used instead of oil, the cost on 80 000 sq yd was $0.0044 per sq yd. The highest cost on these roads was $0.0233 per sq yd, on a road which had been down but 1 year and where the average daily traffic consisted of 350 automobiles and 90 vehicles with steel tires. On the same type of road as the above, but where tar was used and where the work had been completed 2 years, the cost on 42 000 sq yd was $0.0064 per sq yd. On a bituminous gravel concrete road crust, where asphalt was used, the cost on 20 000 sq yd built in 1913 was $0.0098 per sq yd. On a tar concrete road crust constructed in 1910 the yearly cost had been $0.0049 per sq yd, including a seal coat of tar oil applied after the pavement had been down 2 years.

Brick and Cement-Concrete Pavements. It is extremely difficult to obtain much data regarding repairs to brick and concrete pavements. See Sects. 20 and 21. Maintenance costs per square yard on twelve different brick pavements in New York State has varied from $0.000 to $0.052; only one, however, cost nothing. The lowest cost of any where a figure is given is $0.0014. The average, not figuring yardage, was $0.0158. These roads have been in use from 2½ to 6 years.

On 13 concrete pavements that had been laid from 1 to 2 years, and surfaced with a preparation of tar, the cost ranged from $0.000 to $0.0691 per sq yd. On one pavement, however, that had been laid 2 years and had received a surface treatment of hot oil, the cost of repairs was $0.0544 per sq yd. The average for the 13 roads was $0.0252.

On a concrete pavement in Wayne County, Mich., ½ mile long, 9 ft wide, lead-

ing southerly from the town of Wayne, the cost of repairs in 5 years was but $26, and the road in 1914 was in good condition. The Chairman of the Board of Road Commissioners of that county states that it is expected that their pavements will cost on an average not more than $30 per mile per year for repairs.

Comparison of Maintenance Costs. Table II shows the cost of repairs to different kinds of pavements and road crusts in the City of Liverpool as worked out by Brodie, the cost being, as will be seen, not only per yard of surface, but also in tons of traffic per mile. These figures are valuable and probably the only ones of the kind that are available.

Table II

Pavement	Tons per Yard Width per Annum	Life years	Life Tonnage per Yard Width	Cost per Square Yard of Surface	Annual Cost Including Proportion of Capital and Maintenance per Square Yard	Ton Miles per Yd Width per Penny	Cost in Pence per Traffic per Mile (cent)
6-in Sets..........	524 000	18	9 432 000	10/—($2.43)	$8\frac{3}{4}$d ($0.18)	34.0	.029 (0.06)
4-in Sets..........	150 000	50 Est	7 500 000	7/6d($1.83)	$3\frac{1}{2}$d ($0.07)	24.0	.040 (0.08)
Hardwood.........	162 000	17	2 754 000	13/6d($3.29)	$12\frac{1}{2}$d ($0.25)	7.4	.136 (0.27)
Softwood..........	204 000	18	3 672 000	8/6d($2.07)	$7\frac{1}{2}$d ($0.15)	15.5	.064 (0.13)
4-in Pitch macadam	120 000	11	1 320 000	3/—($0.73)	$3\frac{1}{3}$d ($0.07)	20.6	.048 (0.10)
7-in Water-bound macadam.......	120 000	1	120 000		9d ($0.18)	7.6	.132 (0.27)
7-in Water-bound macadam, tar sprayed.........	120 000	2	240 000	1/—($0.24)	6d ($0.12)	11.4	.090 (0.18)

Note. Tonnages on Roads Board basis, except that exceptionally heavy traffic is based on estimated total actual weights.

Conclusion. The values assigned, therefore, for maintenance, are: Granite block 10, wood block 8, sheet-asphalt 6, brick 6, and Bitulithic 6.

7. Annual Cost of Pavements

An engineer who has charge of the construction, maintenance and renewal of a large amount of pavement will be governed more by ultimate economy than first cost. He must take into consideration, too, the interruption to travel by too frequent repairs. A material that might be figured out as economical, even if short-lived, by reason of its cheapness both of first cost and renewal, might require so much attention as to be an actual nuisance.

Annual Cost Formula. Taking the costs and lives of the different pavements as stated in Sects. 5, 6 and 8, the actual annual expense of each for a period as near 50 years as will be convenient for each material can be easily maintained and compared by the formula:

$$A + CI + \frac{R}{N} = \text{ANNUAL EXPENSE},$$

in which A represents the sinking fund to be paid each year to equal C at the end of N years; C, the first cost per square yard; I, the rate of interest; R, the estimated total cost of repairs if distributed over the entire life of the pavement; and N, the life in years of the proposed pavement.

For Granite Block Pavement: $C = \$3.50$; $I = 0.04$; $R = 2.00$; $A = 0.084$; $N =$ 25 years.

Substituting in the equation, $\$0.084 + 0.14 + \frac{2.00}{25} = \$0.304$ FOR FIRST PERIOD.

For the SECOND PERIOD, assuming the value of the concrete to be \$0.70 per sq yd, making the cost of relaying \$2.80 per sq yd, the annual expense is found as before to be \$0.2512, or for 50 years an average of \$0.2776.

For Wood Block Pavement: $C = \$3.50$; $I = 0.04$; $R = 1.00$; $A = 0.1176$; $N =$ 20 years.

Substituting, $\$0.1176 + 0.14 + \frac{1.00}{20} = \$0.3076$ FOR FIRST PERIOD; for SECOND PERIOD \$0.24604, and for 50 years an average of \$0.2706.

For Sheet-Asphalt Pavement: $C = \$2.00$; $I = 0.04$; $R = 0.72$; $A = 0.0714$; $N = 18$ years.

Substituting, $\$0.078 + 0.08 + \frac{72}{18} = \$0.198$ FOR FIRST PERIOD.

For any SUBSEQUENT PERIOD, assuming the cost of repaving to be \$1.25 per sq yd, the expense will be \$0.13875 per sq yd, and for 54 years an average of \$0.1585.

For Brick Pavement: $C = \$2.25$; $I = 0.04$; $R = 0.60$; $A = 0.1123$; $N = 15$ years.

Substituting, $\$0.1123 + 0.09 + 0.04 = \$0.2423$ FOR FIRST PERIOD.

For any SUBSEQUENT PERIOD, assuming cost of repaving to be \$1.55 per sq yd, the annual expense will be \$0.1793, or an average for 45 years of \$0.20 per year.

For Bitulithic Pavement: $C = \$2.35$; $I = 0.04$; $R = 0.72$; $A = 0.09165$; $N =$ 18 years.

Substituting, $\$0.09165 + 0.094 + 0.04 = \$0.22565$ FOR FIRST PERIOD.

For any SUBSEQUENT PERIOD, the cost will be \$0.17035, or an average of \$0.19 for 54 years.

Table III shows the above results condensed.

Table III

Material	First Cost per Square Yard	Expense per Sq Yd for First Period	Expense per Sq Yd for 50 Years
Granite block	\$3.50	\$0.3040	\$0.2726
Wood block	3.50	0.3076	0.2706
Sheet-asphalt	2.00	0.1980	0.1585*
Brick	2.25	0.2423	0.2000†
Bitulithic	2.35	0.2257	0.1900*

*54 years. †45 years.

Conclusion. These estimates give to granite block a value of 21, creosoted wood block 16, brick 12, sheet-asphalt 15, and Bitulithic 15 which are, of course, the same as given for DURABILITY, see Art. 8.

8. Durability of Pavements

The life of these pavements varies greatly according to conditions, so that any conclusion must be extremely general. For instance, a granite block pavement could be laid upon a residential street where the traffic was light and where it would last almost indefinitely. On the other hand, sheet-asphalt pavement could be laid on a street where the traffic was heavy and where its life would be measured by months almost rather than by years. It is stated by the engineer in charge of the pavements of Paris that on

certain streets rock asphalt pavements would not last more than 2 years while on others it would last 13 or 14 years. In considering the durability of different kinds of paving material as a whole it must be assumed that all of the streets of the city are paved with such material as is particularly adapted to the needs of each street, and that a heavy traffic street is paved with a material suitable for heavy traffic, and a light traffic street with a material that is inexpensive but is sufficient for the needs of the street. There are two ends to all pavements, a physical and an economic end. The former comes when the material is so worn out that it cannot be repaired and must be relaid; the latter when the cost of repairs is so great that it will be economy in the end to relay at once. The former test will generally be applied to stone, block, brick, or wood block pavements, and the latter to sheet-asphalt.

When a pavement is made of moderately sized parts of practically the same character, the wear on the parts is about the same over the greater part of the surface, and to repair it requires taking up the old material and replacing it with new rather than adding to the material itself on the street. The necessity of these repairs, and their extent, can generally be determined by an inspection, but when a pavement is made up of parts so small that they must be consolidated into a continuous whole it is different. Sheet pavements, like sheet-asphalt and Bitulithic, wear away by degrees and can be added to in whatever quantity it may be desired and their physical life prolonged indefinitely.

The Economic Test to Ascertain When Repairs Must be Stopped and a New Pavement Laid is as follows: Assume a street to be paved and to have arrived at such a condition that the expense of keeping it in repair is so great that the question arises, shall it be repaved or repairs continued? This question can be settled by the following formula discussed in Art. 7: $A + CI + \frac{R}{N}$ = ANNUAL EXPENSE OF NEW PAVEMENT. Take, for instance, a sheet-asphalt pavement, and let $N = 18$ years, $C = \$2$, $I = 4$, and $R = \$0.72$. Then A will equal \$0.0702 and the equation becomes $\$0.0702 + 0.08 + 0.04 = \$0.1902$, or if the street be repaved, it will cost annually \$0.19 till it is renewed. Consequently if the life of sheet-asphalt be correctly assumed at 18 years, it should not be repaved until the annual cost approaches \$0.19 per sq yd. Assuming the life to be 20 instead of 18 years and applying the formula as before, the annual cost will be reduced to \$0.1872 per sq yd. This is the scientific, the engineering, and the only true way of telling when a sheet-asphalt pavement should be relaid. The only element to modify this principle is the inconvenience to traffic and property owners on the street are put to while repairs are being made. The determination of this must be made in each case. But the principle of the formula is correct, and when cities have had a larger experience with sheet-asphalt pavements, and repair accounts are kept in a more intelligent way, there will be no difficulty in determining the variables.

Life of Pavements. The lives of different paving materials are governed by many different conditions as is illustrated by statements relative to how long the different pavements last in various cities.

Wood Block Pavements. ENGLAND. In London, a wood block pavement on the Strand, from Trafalgar Square to Charing Cross, was relaid in 1913 after it had been in use for 12 years. It is extremely doubtful if there is another street in the world that sustains as great a traffic as this street per yard of width, altho the tires of the vehicles are mostly of rubber and the wear and tear on the blocks are probably not as great as in other cities with less traffic but where the vehicles are steel-tired.

The life of another wood block pavement in London, on Gracechurch St., laid in 1913, was estimated by the assistant engineer of the city at 5 years, altho the contractor estimated it at 15 years. Wood (4) states that the Local Government Board of London has defined the life of soft wood block pavement at 7 years and of hard wood block at 10 years. Wood, however, states that if the actual life of the wood pavements in London had been considered, it would be found that there would be a very small amount that had been removed within 10 years, and that the average life would more probably be 12 to 15 years. But referring to actual wear he states that, from his observations, it has been found that the life of the best Swedish soft wood block, with a traffic of 100 tons per ft effective width of roadway per day, would be 0.061 in per annum. This is a positive and definite statement, and if a definite standard of traffic could be obtained, such a statement would be of greater and very positive value. Brodie, City Engineer of Liverpool, estimates that a soft wood block pavement will sustain a traffic of 3 672 000 tons per yd of width, and in that way he figures out the life of a pavement with its known traffic. These statements assume that the pavement will wear out rather than rot out, and if the amount of traffic comes during the physical life of the pavement, this may be true, but if it is distributed over a long term of years, it is questionable whether the assumption would hold good. In Sheffield, England, the average life of wood block pavement is about 13 years. It is said that on the Edgeware Road, Hampstead, England, where the traffic amounts to about 10 000 vehicles of all kinds in 12 hr, the actual wear on Jarrah paving blocks in 6 years amounted to only ¼ in. In Birmingham, England, the wear on the creosoted Swedish wood blocks in the business streets was said to be about ¼ in per annum.

Germany. In Berlin it is considered that the soft wood block pavement will last 12 years and the hard wood two or three times as long, altho the latter has not been laid to any great extent. In Breslau, on light traffic streets, wood block pavement is said to have lasted 25 years.

In Paris the life of the wood block pavement on the Champs Élysees is about 7 years, while the average over the entire city is 8 years. It must be remembered, however, that in Paris as a rule the heavy traffic streets are paved with wood blocks.

In Melbourne, Australia, it is said that red gum blocks, on fairly heavy traffic streets, in some instances lasted 24 years; and in South Melbourne, on a fairly heavy traffic street, with annual tar painting, the blocks had lasted 22 years and are still in use. On another street the blocks had been laid and in use 12 years with no apparent wear; the surface, however, had been tarred and sanded each year.

On Clinton Ave., Brooklyn, N. Y., a portion of a wood pavement was taken up after it had been in use 10 years, when the wear was found to be ¼ in. The traffic on this avenue is fairly heavy. The blocks were of long leaf yellow pine, treated with creosote and rosin.

Rock Asphalt Pavements. England. With a rock asphalt pavement, Wood estimates that a traffic of 100 tons per day per ft of width of pavement will wear the pavement 0.02 in per annum. Knowing the amount of traffic, the life of the pavement can readily be deduced. It is difficult to ascertain what is considered as the life of rock asphalt pavements in many foreign cities, as long maintenance contracts are made which cover more than simple repairs.

Sheet-Asphalt Pavements. United States. In America very little data has been kept which will give information of much value. In the report of the Bureau of Engineering of Buffalo for the year ending June 30, 1913, when over 1 000 000 sq yd of pavement had been replaced, the average age of the pavements relaid on streets where there were no car tracks was 18.29 years, and on streets with car tracks 16.85 years, and the average age of all was 17.48 years. In the City of Washington, D. C., the life of a sheet-asphalt pavement is taken as 20 years.

Stone Block Pavements. Europe. What has been said of sheet-asphalt is true as to the life of stone block pavements, altho in general the officials of different foreign cities give the average life of granite block pavements as follows: Glasgow, 50 years; Edinburgh, 30 years; Liverpool, 30 years; Paris, 30 years. These figures, even if correct, could not be applied to this country, as many residential streets in European cities are paved with stone, so that the life of the pavements is unduly long.

United States. From data collected from American cities the estimated life of granite block is taken at 25 years, creosoted wood block at 20 years, brick at 15 years, sheet-asphalt at 18 years, and Bitulithic at 18 years.

Table IV.—Annual Rates of Wear of Pavement Under Known Weights of Traffic (17)

	Kind of Pavement	Tons in 24 Hours	Road'y Width in Feet	Tons per Foot per 24 Hr.	Annual Wear in Inches	Rate of Wear per 100 Tons
Brooklyn Bridge..........	Granite	4172	8	522	0.2500	0.0490
Penn. R. R. Ferry at foot Cortland St. roadway....	Wood	2301	10	230	0.4870	0.2117
D. L. & W. Ry. Entrance at West 23rd St...........	Granite	6509	21	309	0.0202	0.0065
Atlantic Ave. Ferry at foot Whitehall St...........	Wood	1004	14	72	0.0501	0.0696
13th St. and 7th Ave. to Greenwich St...........	Sheet-asphalt	1650	30	55	0.1000	0.1820
14th St. from Ave. A to B...	Sheet-asphalt	2000	40	50	0.1470	0.2940
31st St. from Lexington to 3rd Ave...............	Rock asphalt	1500	30	50	0.1103	0.2206

Table V.—Consensus of Opinion of Canadian Engineers as to Durability (11a).

Pavement	Small Repairs	Extensive Repairs	Complete Recon-struction
	Years	Years	Years
Asphalt block......................	5 to 10	10 to 12	12 to 15
Asphalt concrete..................	4 to 6	6 to 8*	8 to 10*
Bitulithic..........................	5 to 8	10 to 15	15 to 20
Brick..............................	8 to 10	10 to 15	15 to 18
Cement-concrete..................	5 to 8	10 to 12	15 to 18*
Scoria block and stone...........	10 to 15	15 to 20	20 to 30
Sheet-asphalt.....................	4 to 8	10 to 15	15 to 18
Untreated wood block............	3 to 5	6 to 10	10 to 12
Treated wood block...............	8 to 10	12 to 15	15 to 18*

*These pavements have not attained an age in Canada sufficient to place the figures beyond conjecture.

Opinions of Canadian Engineers as to Nature of Deterioration (11a).

"Asphalt Block: Edge-wear forming holes and cobbles; worn pavement noisy and hard to keep clean; disintegration of bottom of blocks.

"Asphaltic Concrete: Wears in holes; susceptible to marking in hot, sunny weather.

"Bitulithic: Wears evenly, with a tendency to holes under heavier traffic; susceptible to surface marks in hot weather.

"Brick: Edge-wear and cobbling under heavy traffic; increased noise and unsanitariness as wear increases; when worn badly it slows down traffic.

"Sheet-Asphalt: Wears slowly into large holes or patches; heavy traffic causes ruts; cracks hasten deterioration.

"Wood Block: Rots rapidly if untreated, retarding traffic; treated block wears slowly and evenly; frost intrusion causes buckling.

"Stone and Scoria Block: Wears gradually into holes and cobbles; unsanitary when roughened.

"Cement-Concrete: Wear is slow and even if well placed; cracking and chipping develop otherwise."

Conclusions. In view of the data at hand, granite block is given a value of 21, wood block 16, brick 12, sheet-asphalt 15, and Bitulithic 15.

9. Easiness of Cleaning Pavements

Some figures have already been given showing the benefits of smooth pavements when they are to be cleaned. How necessary this is can be recognized from a statement made by a committee of the Society of Arts, London, in 1875, to the effect that at that time it was estimated that 1000 tons of horse manure was being dropped daily upon the streets of London. This had to be taken up and removed to avoid being incorporated into the human system thru the respiratory organs. These figures, too, would be revised as applied to 1918 on account of the use of the automobile both for pleasure and for business. Other refuse of all kinds, however, collects upon the streets, and the pavement that uniformly presents a hard, smooth and even surface is cleaned at much less expense than one that is rough and uneven.

In 1907 a Commission in New York City appointed by the Mayor to investigate the entire matter of street cleaning made a report from which the following quotation is taken.

"There is a very marked difference between the quantity of dust left upon the pavements of various kinds. Thus, if the average volume and weight collected from the sheet-asphalt pavement is called 100, the relative quantities from other kinds of pavements were:

	Volume	Weight
From sheet-asphalt	100	100
From asphalt block	180	182
From wood block *	332	145
From granite block	1081	912

*It should be said that the wood block pavement on which the examination was made is one of the oldest of its kind in the city, and its surface, being uneven, caught and held an unusual quantity of dust. Wood block pavement, when comparatively new, should compare favorably with asphalt block pavement in its freedom from dust retaining qualities.

"After careful consideration of all the facts available, the average relative cost of cleaning, equally well, the various kinds of pavement in use in the city under similar conditions of repair, is estimated as follows:

Sheet-asphalt pavement	100
Wood block pavement, new	105
Asphalt block pavement	115
Brick pavement	120
Wood block pavement, old	125
Medina block pavement	130
Granite block pavement	140
Belgian block pavement	150
Cobblestone pavement	3000

"On the assumption of 100 cleanings per year it may be shown that the annual cost of cleaning equally well a mile of each of the pavements named, over what it would be if sheet-asphalt were substituted, would be as follows:

Wood block pavement, new	$26.40
Asphalt block pavement, average condition	79.20
Brick pavement	105.60
Wood block pavement, old	132.60
Medina block pavement	158.40
Granite block pavement	211.20
Belgian block pavement	264.00
Cobblestone pavement	1584.00"

Philadelphia. Connell (12) gives the average cost of cleaning different kinds of pavement per 1000 sq yd in 1914 as follows: Granite block, $0.245; brick, $0.217; wood block, $0.217; sheet-asphalt. $0.187.

Conclusions. Taking all things into consideration, granite block is given a value of 10, wood block 14, sheet-asphalt 14, brick 15, and Bitulithic 14, always upon the assumption that the pavements are kept in good condition.

10. Resistance to Traffic on Pavements

Many experiments have been made to determine the force necessary to draw a given load over roads and pavements of different character. The most of them, however, were made many years ago, and, while doubtless correct at the time, were made upon pavements so entirely different in character and construction that they are not of much value at the present time. The tractive force, or the power necessary to move vehicles or loads, is measured generally in pounds per ton. In order to start a load that is stationary the power must be strong enough first to overcome the inertia of the load, then the rise in the grade, if it be up-grade, and then to overcome the friction of the moving load. The amount of power necessary to draw a load up a given grade can be figured theoretically, but so many different conditions must be taken into consideration that figures are not of much value. A great many experiments have been made at different times to ascertain the resistance to traffic on the different pavements, but the results have differed greatly. This can easily be understood when it is remembered how different the tractive force necessary to move a load on any pavement varies according to the condition of the pavement. The tractive force required to move a load on a sheet-asphalt pavement in perfect condition would vary according to the temperature of the pavement and the weight of the load. If it were so light as not to sink into the sheet-asphalt, no matter how soft it might be, there would be no particular difference, but in the summer time, under the heat of the sun, as a rule all sheet-asphalt pavements soften so that the tractive force is greatly increased. On a block pavement, whether stone, wood, or brick, the relative smoothness of the pavement has everything to do with the tractive force required to move a load. The general surface of a stone pavement can be smooth, but if the blocks themselves are bunchy, it will often be necessary to lift the wheel possibly ¼-in over a bunch, when on a dressed block the surface would be smooth and the tractive force required much less.

Experiments can be made, of course, under conditions that will give comparative results. At the Atlanta Exposition, in 1895, the U. S. Dept. Agr. made some experiments which resulted in giving a traction of 26 lb for poor sheet-asphalt, 54 lb for cobblestone, 42 lb for poor block pavement, 38 lb for the best macadam, and 320 lb for loose sand. Haupt (18), in 1889, gave results varying from 10 lb for iron trams to 400 lb for sand, the pavements being: sheet-asphalt 15, good Belgian block 33, stone block 80, French macadam 40, good cobble 133 to 66. Certain other experiments for sheet-asphalt under different conditions ranged from 15 to 26. The opinion among engineers is that the tractive force varies inversely as the diameter of the wheels. but some say inversely as the square root of the diameter. W. Hewitt, of England, says: "From experiments made with Eastren and Anderson's horse-dynamometer at the Royal Agricultural Show in 1874, a slightly greater ratio than inversely as the diameter was given, and hence inversely as the diameter is the more correct view of the two." See Sect. 4.

Test With Motor-Truck by Kennelly and Shurig (20). "By tractive resistance is meant the horizontal force necessary to apply to the truck in order to keep it at a constant speed in still air after deducting axle frictions and internal-mechanism losses. It is, therefore, the reactive force offered by the truck, assumed internally frictionless, in overcoming the road, tire and still-air resistances on a level surface. It may be expressed either in pounds weight per short ton of total moving mass, or in kilograms per metric ton, or in percent equivalent grade. Thus

a 1% equivalent grade tractive resistance means that a car without axle friction or internal mechanism losses would require to be pulled on a level road at a constant stated speed a force of 20 lb per short ton of 2000 lb, in order to overcome the resistance of the tires, road-bed and still-air displacement.

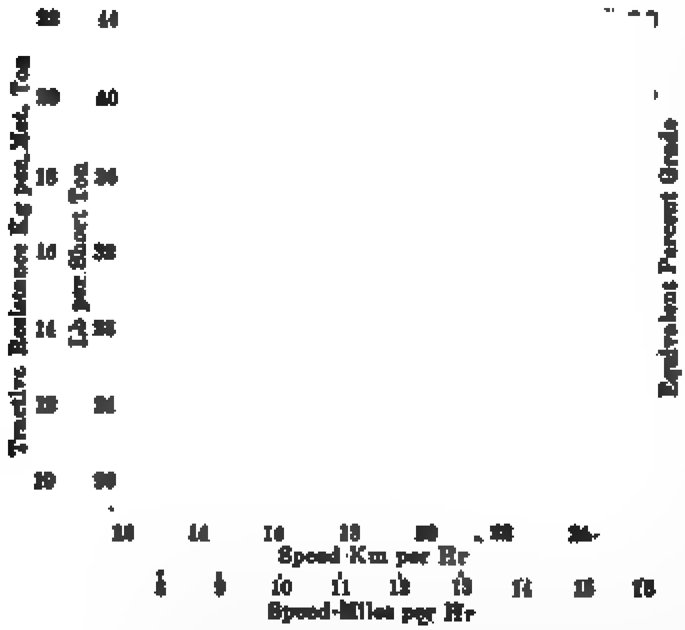

Fig. 1. Summary of Tractive Resistance Tests

"The truck tested was a 1000-lb (450 kg) electrically-propelled delivery wagon equipped with single solid rubber tires, one on each of the four wheels, the tire rating being 36 by 2½ in (915 by 63.5 mm). The tests were made by running the car at, as nearly as possible, constant measured speed, in alternate directions, over selected lengths of standard roads in and near Boston.

"The following urban pavements are enumerated in the order of their desirability for vehicle operation from the point of view of tractive resistance at 12.4 miles per hr, as found in this investigation. (1) Asphalt, (2) wood block, (3) hard smooth macadam, (4) brick, (5) granite block with cement-filled joints, (6) cinder, (7) gravel, (8) granite block with sand-filled joints (see Fig. 1). The presence of a layer of dust, say 1 cm thick, on a fair macadam road, was found to increase the equivalent grade of tractive resistance at a speed of 20 miles (12.4 km)."

Conclusions. From all these figures it is believed, taking into consideration the varying conditions under which all tests were made, as well as the improved character of pavements at present, and remembering that the resistance to traffic increases very much on the bituminous pavements in hot weather, that the following values should be assigned: Granite block 13, wood block 14, brick 15, sheet-asphalt 11, and Bitulithic 12.

11. Slipperiness of Pavements

A great many conditions affect this property, such as cleanliness, temperature, condition of the pavement, whether wet, damp, or dry, etc. Wood block pavement, for instance, while dry, is not slippery, but while wet is exceedingly so, especially if not clean. Then, too, materials can be laid in such a way as to modify materially the normal slipperiness of the pavement. It is, however, an important quality, as it affects directly the efficiency of the horses, if the vehicles are horse-drawn; and if motor vehicles, a pavement may often become so slippery as to be impassable.

Haywood made some very extended observations as to slipperiness in London in 1873. Without attempting to cite in detail the experiments made, the conclusions can be given. The true order of slipperiness is that a horse would travel 132 miles on granite block, 191 miles on rock asphalt, and 446 miles on wood block without accident. It must be understood, however, that the asphalt referred to was the European rock asphalt, which is more slippery than the American sheet-asphalt, and that the soft woods used in Europe are much less slippery than those in America. This is illustrated in Berlin, where the business section is almost entirely paved with rock asphalt, but on the approaches to the bridges over railroad tracks and the River Spree, where there is a grade possibly of 2%, wood block pavement is always laid. In summing up Haywood said: "Taking the whole group of conditions into account, the rock

asphalt was the most advantageously placed, the wood block was the next so, and the granite was the worst placed. On the average of the whole 50 days' observations, the granite block was found to be most slippery, the asphalt, next so, and the wood the least. Separating the accidents under these conditions of surface as regards moisture, it appears that rock asphalt was most slippery when merely damp, and safest when dry; that granite block was most slippery when dry, and safest when wet; that wood block was most slippery when damp, and safest when dry."

Greene, in 1885, had a series of observations made in ten of the principal cities of the United States to determine the relative slipperiness of pavements. From these results it was decided that on pavements in American cities a horse would travel 272 miles on wood block, 413 on granite block, and 583 on sheet-asphalt without an accident. The accidents were divided also into falls upon the knees, falls upon the haunches, and complete falls. On a rough pavement falls upon the knees should not be wholly charged to slipperiness, as a great many must be caused by stumbling. Greene found that, of a total of 84 falls, 68 were upon the knees. Assuming that one-half of the latter were stumbles only, the deduction would be that a horse would travel 698 miles on granite block without an accident due to slipperiness. These results, of course, are general.

Table VI

Kind of Roadway	Maximum Grade
Gravel	12.0%
Broken stone	12.0%
Bituminous surface	6.0%
Bituminous macadam	8.0%
Bituminous concrete	8.0%
Sheet-asphalt	5.0%
Cement-concrete	8.0%
Brick, cement grout filler	6.0%
Brick, bituminous filler	12.0%
Stone block, cement grout filler	9.0%
Stone block, bituminous filler	15.0%
Wood block	4.0%

The Spec. Com. Mat. Road Cons., Am. Soc. C. E. (6c) recommend, in 1918, the maximum limits for grades for different kinds of roads and pavements as given in Table VI.

Table VII.—Number of Cities Using Maximum Grades Given (7)

Percent	Wood Block	Grouted Brick	Sheet-Asphalt	Cement-Concrete	Bituminous Concrete	Bituminous Macadam	Water-bound Macadam
20	..	1	..	1	..	..	..
16	..	..	..	..	..	..	1
15	..	1	..	1	..	..	4
14	..	1	..	1	..	1	1
12	..	..	..	..	1	1	2
11	..	..	..	1	1	..	3
10	..	1	1	1	1	4	3
9	..	1	..	..	..	1	..
8	..	4	..	2	1	2	2
7	1	1	..	2	3	3	..
6.5	..	..	..	..	1	..	..
6	1	4	..	1	8	2	..
5	3	7	9	3	3	2	2
4.5	..	..	1	..	..	..	..
4	3	1	4	3	1	..	..
3.5	..	..	..	1	..	..	..
3	5	1	3	2	..	1	..
2.5	3	..	1	..	..	..	..
2	5	1	..	..	..	..	1
1.5	..	..	1	..	..	..	..
1	1	..	..	..	..	..	..
0.5	2	..	..	..	..	..	..
0.4	..	..	1	..	..	..	..
Total number of cities	24	24	21	19	20	17	19

Conclusions. From these and personal observations, granite block is given a value of 7. wood block 4, sheet-asphalt 5, brick 6, and Bitulithic 6.

12. Favorableness to Travel on Pavements

This is a difficult property to reduce to a cash basis. Some engineers say that the amount of noise made by driving a wagon over different kinds of pavements shows the relative amount of damage caused to the wagon. While this may seem a strange standard, it is a logical one, as it is well known that the smoother the pavement the less noisy it is.

Investigations in the United States. In response to an inquiry as to the difference in wear and tear to delivery wagons and horses when the sheet-asphalt pavements of Brooklyn, N. Y., were increased from 15 to 65 miles in a total pavement mileage of about 500, two of the largest dry goods firms said: (1) "We desire to say that there is a very appreciable difference in our wear and tear account since the increase of asphalt pavements. No more damage has been done to our horses, and of course it goes without saying that the saving to wagons must be very great;" (2) "We beg to state that the effect of the pavements of this Borough has been of such a character as to save us considerable wear and tear on our wagons, and lameness to our horses."

In 1896 the Poughkeepsie Cab and Transfer Co. of Poughkeepsie, N. Y., said in answer to an inquiry: "We would say that our repair bill for 1895 was 50% less than in 1894, and our shoeing bill 42% less in 1895 than in 1894. We attribute this in a great measure to the introduction of smooth pavements in our city." Poughkeepsie at that time had about 28 000 sq yd of asphalt block pavement.

Investigations in London. In 1889 the following two questions were put to the omnibus drivers of London: 1st. Which do you consider the best form of roadway to drive over? 2nd. Which the worst? The answers were: 1st. 750 wood block; 219 macadam; 197 granite block; 51 rock-asphalt. 2nd. 122 wood block; 1 macadam; 13 granite block; 1045 rock-asphalt. It must be remembered, however, that the asphalt pavement is that laid of natural rock and probably subjected to as bad a climate for slipperiness as that of any city in the world. The condition in which a pavement is kept affects different pavements differently. An editorial note in Engineering in 1876 says: "Cornhill was blocked for nearly an hour thru the falling of horses, and the scenes in Cheapside, Eastcheap, Mowgate St., are simply disgraceful, not from the fault of the paving of the roadway, but simply because it is not kept clean." This referred to rock asphalt.

Conclusions. The values given to different pavements are: granite block 2, wood block 5, sheet-asphalt 4, brick 3, and Bitulithic 4.

13. Sanitariness of Pavements

There is a great difference in the sanitary value of the pavements under consideration.

A Committee of the Society of Arts in London, previously referred to, made the following statement on this point: "In urban districts which have been well drained with proper self-cleansing sewers and freed from emanations from them, fever has been found to lurk in those quarters where the surface paving and surface cleaning are bad. On the other hand, the extension of impermeable pavements has been attended with a marked reduction of malarious disease."

In the Old City of New York the number of deaths in 1892 was 44 329, and in 1914, in the same area, the deaths were 43 253, altho the population had increased from approximately 1 630 000 in 1892 to 3 296 197 as estimated by the Department of Health for July 1, 1915. This is a remarkable record, and while of course it is accounted for by the increase in sanitary measures as a whole, the result has been attained to quite an extent by the laying of smooth and sanitary pavements on the East Side and in the tenement districts, where the population is denser than in any other city in the world. It has been possible to keep the streets clean, and they serve largely as recreation grounds for the people in the evenings and on Sundays.

The principles given above are unquestionably correct, and consequently any pavement with a smooth, impervious surface ranks high. Granite block and brick come under that head, but they are noisy, and noise must be considered in this connection. Noisy streets affect one's nervous system,

and a noiseless pavement should be laid in front of hospitals, schools, churches, etc. If the joints of a pavement are open, they allow moisture to collect and street refuse in general to accumulate. This latter decays and gives off not only offensive but dangerous odors.

Conclusions. As a sanitary pavement, then, granite block is given a value of 9, wood block 13, sheet-asphalt 12, brick 10, and Bitulithic 12.

PROPERTIES OF ROADS

14. General Considerations Relative to Roads

The construction of roads in America did not receive much attention until about 1890, when the question of good roads has been brought into prominence by the advent of the bicycle, followed by the introduction of the automobile and its rapid increase both for pleasure and business purposes. The study of the different kinds of roads is more difficult than that of pavements, because the different forms of road construction have not been standardized, even when the same materials have been used, and not enough data has been collected to form a positive and definite idea of the durability of the different kinds or the cost of maintenance. The principles laid down in the selection of materials for pavements are applicable to a certain extent to the selection of materials for roads, but, if possible, the study is even more important, as in the question of pavements a street that is well built up requires a pavement, even if the traffic upon it is not great, for sanitary as well as esthetic reasons, while a road is improved simply on account of its traffic. The principles proposed for road materials are that they shall be cheap, durable, easily maintained, present light resistance to traffic, and be not slippery. Sanitariness, easiness of cleaning, and favorableness to travel are not of great importance, as the roads are in the country and built up to a very slight extent.

Wear of Roads. The GERMAN ENGINEERS reported to the 3rd Int. Road Cong. that the wear of road surfaces produced by fast running passenger motor-cars is due to the following causes: The abstraction of the fine and finest binding and filling materials from the roadway by the suction and propulsion produced by fast revolving wheels, which is the cause of the well known dust nuisance in dry weather and objectionable mud slinging in wet weather. The mechanical crushing of the road material by the heavy blows at very high speeds from the steel rivet heads or studs of the various anti-slipping devices with which the majority of motor-cars are now fitted. The loosening of the top layers of the roadway at sharp bends, generally on the inside, by the gliding motion of the tires producing abrasion and dislocation of the road material, the motion being due partly to the centrifugal force and partly to the rigid connection between wheels and axle. Another cause which they held responsible for the abnormal, violent destruction of road crusts by heavy motor traffic are the iron tires with which some motors and most of the trailers are fitted. It was said that all engineers are asking for regulations specifying that heavy motors and trailers should only be allowed to be built with rubber tires; that it is a fact proved by experience that, owing to the very much higher speeds of mechanically propelled wagons, and their weights being usually heavier than those of wagons drawn by animals, they absolutely ruin macadamized roads with their iron tires, and even roads paved with small setts are damaged by them everywhere, because the tires chip off the edges of the stones. It was stated in this paper that after all these experiences, which extend over many years and are the same everywhere, one is bound to arrive at the conclusion that heavily laden motor wagons no longer wear out ordinary macadamized roads, but very quickly destroy them. This leads to the following verdict, which will hold good everywhere: Ordinary macadam roads are not suitable for the regular traffic of motor-wagons or motor-omnibuses.

The determination of the wear of roads is sometimes made by the amount of material

needed to resurface the roads and sometimes by the actual amount the road crust is worn down. HEWES, in reporting to the 3rd Int. Road Cong., stated that by records which have been kept by the Mass. Highway Comm. on 55 separate sections of macadam road for the 6 years ending in 1907, where the amount of stone required for resurfacing was accurately recorded, it was shown that the annual coefficient of wear was 0.023 tons per sq yd, but that the traffic upon the roads during that period was not known, and that the only information to be derived from these figures was that water-bound macadam roads wore out during an interval of between 6 and 7 years so that they required resurfacing. These roads were largely surfaced with trap rock.

Suitability of Roads for Different Local Conditions. The following opinions were presented by official reporters to the 3rd Int. Road Cong. held in London in 1913.

The Engineer of Alexandria, Egypt, stated that the ideal road may be realized by the construction of a concretional mass of carefully calculated thickness, based on the factors of velocity and weight of the load and the solidity of the subsoil, protected by an elastic and easily renewable wearing surface of just sufficient thickness to give a reasonable number of years' wear, and to resist climatic and vibratory actions. This elastic skin will possibly be much thinner and harder when horse-drawn vehicles have been altogether abandoned.

The French Engineers in their summary state that superficial tarring, which has proved its efficacy in preventing in summer the superficial disintegration of roads under light and fast traffic, has developed greatly, so that it is now important to consider practical means of preserving the coating by repairing the small cracks. When heavy traffic, motor or otherwise, is added to the light traffic, the superficial tarring is no longer sufficient, especially in winter, or on roads ill-exposed, ill-aërated, and constantly damp. Therefore, it is not only necessary to consolidate the surface, but also the body of the roadway. The tar concrete, the bituminous macadam, and the systems related to or derived from them tend to this end, each offering to different degrees these two eminently desirable qualities, the compactness of the mass and the cohesion of the constituent parts. With reference to the economic study of the different road crusts, the report concluded by saying that in the very frequent case of an average traffic, including, however, a proportion relatively important of touring automobiles, it will often suffice, in order to avoid the special damage done by automobiles, to constitute the metalling of relatively soft but binding material, and to adopt limestone aggregates, as these give roads more compact and out of which the detritus escapes with difficulty. Also that if the importance and the nature of the traffic require hard metalling, and if the damages are mainly attributable to fast automobiles, everything points to the need of surface tarring; that this tarring in these cases gives excellent results, as much from the point of view of convenience to the traffic as from the economic point of view: it allows, notably, to get the maximum life out of the metalling compatible with its resistance to crushing, so that there is every advantage in employing very strong materials in surface tarred metalling; that this surface tarring does not give good results unless it is maintained, and that likewise, on lengths where automobile traffic is heavy, it may be advisable to give up the tarring by reason of its too rapid wear and of the difficulty of renewing it at convenient times. It was stated that superficial tarring does not sensibly improve the metalling as regards its resistance to pressure and cannot, therefore, be recommended in the case of heavy traffic. The results obtained from the few cases of consolidated metalling laid down in France lead one to hope that these kinds of roads may be suitable in these cases and that, notably, metalling made up of previously tar-coated materials are likely to provide an economical solution of this question.

The English Engineers reporting on construction in speaking of the relative advantages and use of the different bituminous materials say that the question is too complex to express a definite opinion as to the relative advantages, discussed apart from numerous variations in first cost and durability under different volumes and classes of traffic, as these advantages cannot be ascertained with sufficient accuracy to provide reliable data; that when roads have more than average traffic and of a heavier type, the more expensive pitch, tar, oils, and sand matrix are largely employed by the grouting method with satisfactory results.

WOOD, Engineer of the Borough of Fulham, London, argued, that the material

composing the ordinary water-bound macadam road is in itself a much greater wear-resisting agent than the wood block pavement, but if the quantity of detritus removed each year, exclusive of horse droppings, is taken as an indication of the wear, an average macadam road in his district would wear at the rate of 0.2 in per annum, that is, 33% higher than on the wood paving with only 40% of the traffic. If the wear on the macadam road had been at the same rate as on the wood paving in proportion to the traffic, the actual wear should have been only 0.0125 in. It is therefore inferred that the active force in the deterioration of water-bound roads is chiefly the weather. The engineers also state that when the road is frost-bound the wear of a macadam crust is very light, and consequently draw the conclusion that the binding agent which will successfully resist the effects of the weather is the great desideratum. They also contend that a tar-sprayed macadam crust is much preserved during the summer, but consider that tar is detrimental in the winter as it assists in retaining moisture, and if the tar coating is worn thin the road loosens more readily than an untreated one. This conclusion was disagreed with by CROMPTON of the English Road Board.

DRYLAND, County Engineer, Surrey, considers that the efficiency of surface tarring is relative to the intensity of the traffic, and when this exceeds about 20 000 tons per yd width per annum a bituminous-bound road crust is necessary. It was also found that slag tar concrete satisfactorily carried a traffic of 80 000 tons per yd width per annum, and Trinidad asphalt concrete 200 000 tons per yd width per annum.

BRODIE, City Engineer of Liverpool, has probably given the most attention to the actual wear of the road crust itself by actual measurements, and then, by knowing

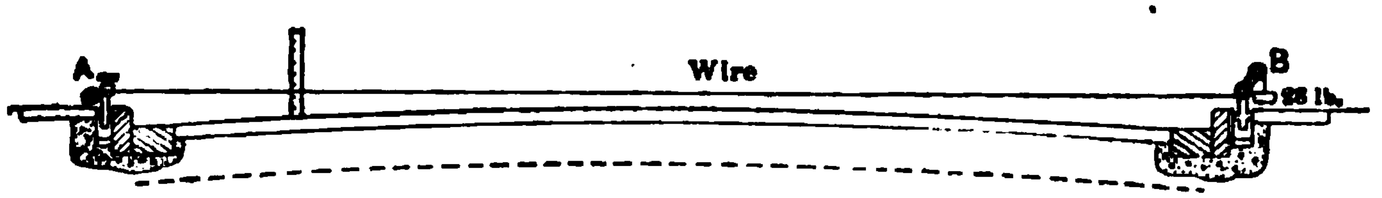

Fig. 2. Method with Wire

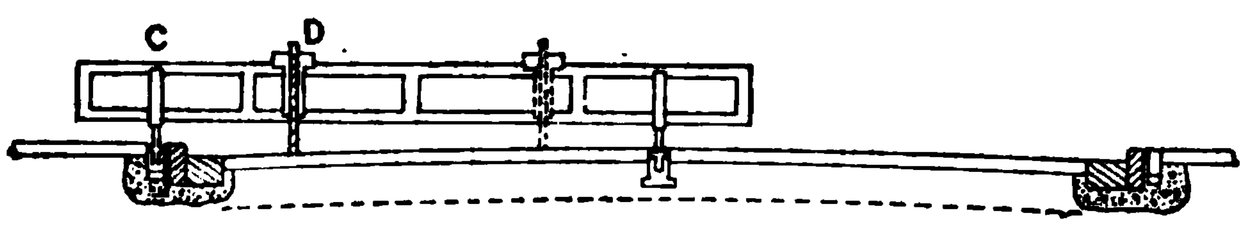

Fig. 3. Method with Straight-Edge

the traffic, is able to learn the effect of the different kinds of traffic. Figs. 2 and 3 show two devices used by Brodie for this purpose, one being a wire stretched tightly, and the other a solid template.

The Italian Engineer concludes his paper on the economic study of the road crusts by saying that in the actual condition of the studies and of practice it is considered that the paving entirely with granite blocks as a road covering gives the best guarantee from the traffic standpoint and from that of a covering on roads with intense and heavy traffic; that superficial tarring is considered appropriate to roads recently rolled and not bearing heavy traffic, but subject to an intense passing of light vehicles and automobiles.

The Swiss Engineer says that on wheel ways within the city other than those in streets with the smallest traffic, surface tarrings have not proved satisfactory, but for country roads the application of surface tarring is, on account of the lessened formation of dust, very much to be recommended, even tho a certain quantity of repairs has to be made every year.

The German Engineers say that, according to all observations made, the wear of macadam roads by light passenger motor-cars still keeps within the limits already reached hitherto on roads where the traffic of animal-drawn vehicles has been brisk and heavy, but that the wear of tar roads caused by light fast running motor-cars is not so great as that caused by vehicles drawn by animal power, because the injurious effect of the animals' shoes is done away with.

From the discussion it will be seen how difficult it is to put a positive value on the different kinds of roads, and also how necessary it is, in order

to determine the proper material for a road crust, to know, not only the quantity, but the quality of the traffic. A country road is improved simply on account of the demands of traffic, and just how it shall be improved will depend upon that traffic as well as the financial ability of the local authorities. Funds are not always available for the road crust that will be the most economical ultimately, but even then the principles underlying road construction should be known and applied as much as possible.

15. First Cost of Roads

The cheapest form of road construction is simply the shaping up of the natural earth and keeping it so shaped thruout the year. This, however, cannot be called really good road construction, nor can any cost be given for original work or for maintenance. It often happens, however, that financial conditions are such, that only such treatment is possible. Another cheap form of construction is what is known as the sand-clay road. This is of two kinds, one where the original soil is sand and clay has to be brought for some distance, and the other, where the original soil is clay and the sand is the material to be brought in. This has been used to quite an extent where traffic is light, and with good results. Its cost varies greatly according to conditions, but Pratt (23) gives the costs of constructing 2563 sq yd of surfacing at 5.21 cents per sq yd, including grading. Here the original soil was sandy and both the clay and sand were hauled in to a certain extent. On another road, where the area was 35 590 sq yd, the cost is given at 5.06 cents per sq yd, the original soil being clay and the sand being hauled. On another road, where the area was 10 000 sq yd and the area surfaced was 6000 sq yd, the cost was 19.6 cents per sq yd. The earth excavation amounted to 3975 cu yd, and the sand used in surfacing was 815 cu yd. It sometimes happens that good gravel can be obtained locally, and consequently a road crust constructed that will give satisfactory results, all things considered, when theoretically gravel would not be a proper material to be used. The cost of this will vary under different conditions, but in general an estimate of 50 to 60 cents per sq yd for a road crust 6 in deep will be a fair average. The cost of repairs will depend, other things being equal, upon the amount and character of traffic. See Sects. 9, 10 and 11 for cost of constructing earth, sand-clay, gravel and broken stone roads.

16. Cost of Maintenance of Roads

In Sects. 9, 10, 11, 13 and 14 will be found data covering the cost of maintenance of earth and sand-clay roads, water-bound gravel and broken stone roads, and gravel and broken stone roads maintained with the aid of dust palliatives and bituminous surfaces respectively.

Examples of the Cost Data on Maintenance of Roads. One of the engineers reporting to the 3rd Int. Road Cong. gives the cost of maintenance on ten different roads for 3 years before motor-omnibus traffic was begun as 12.3 cents per sq yd per year, while in the year following the advent of motor-buses the cost was 25.5 cents per sq yd. While the tonnage was undoubtedly very much increased, there can also be noted that a great portion of this cost was caused by the character of the traffic itself. The figures given for costs by the English engineers show that it costs 1.4 cents to carry a ton a mile on one macadam road and on another one in the same county 0.12 cents only, indicating plainly that the road was not constructed to suit the traffic. The English figures would seem to indicate that when the cost of maintenance exceeded 0.67 cents a ton a mile it was more economical to use stone pavement.

Massachusetts Practice. The cost of maintaining macadam surfaces with cold oil, average of 3 years on about 50 miles, has been $0.0304 per sq yd per year. The cost of

maintaining surfaces composed of mixed sand and oil asphalt, on about 10 miles, was $0.0848 per sq yd per year. This cost, however, includes cost of additional seal coats in a few instances. The cost, not including these seal coats, was $0.025 per sq yd per year. Sohier (24) gives the cost per ton per mile per year on ten different roads in Massachusetts, the cost varying from 0.06 to 0.44 cents. The road costing the least was 15 years old, built of trap rock macadam on a main route. When this road was 8 years old it was resurfaced, and in 1907 ½ gal of the heaviest asphaltic oil that could be applied cold was spread upon the road and properly covered with pea stone and gravel. This treatment was repeated for 2 years, when ¼ gal of heavy hot asphaltic oil was spread upon the road and properly covered. The treatment was repeated once, and the road was said to be in better condition in 1914 than in 1907. The most expensive road for repairs, both per ton and per mile, was a trap rock macadam with heavy teaming. The stones wore down over ½ in in a year. It needed constant patching and was never in excellent condition except when recently resurfaced. It had 2 to 3 in of new stone every 4 or 5 years, and in 1910 it was resurfaced with 3 in of asphaltic macadam at a cost of $1 per sq yd. This road was reported to be in good condition in 1914, but it needed some patching.

17. Annual Cost of Roads

Comparison of Annual Costs of Roads Under Different Traffic Conditions, by Thomas (27).

"A table (see Fig. 4) showing the annual cost and curves for the cost per vehicle-mile of several different types of roads has been prepared and is reproduced herewith. The construction and maintenance costs represent average values from the experience of the Mich. State Highway Dept. during 1915 and 1916, with small amounts added to provide for future betterments. Money is taken as worth 5%. The sinking fund earns 3%, and since most of the roads of Michigan are built with money derived from direct taxation rather than from bond issues it is assumed that the funds will be used for rebuilding or resurfacing as follows: Gravel and water-bound macadam roads resurfaced at the end of 5 years for one-half the original cost, bituminous macadam resurfaced at the end of 10 years for one-half the original cost; concrete resurfaced with bituminous concrete or otherwise rebuilt at the end of 15 years at a cost of $10 000 per mile; brick rebuilt at the end of 25 years at a cost of $13 000 per mile.

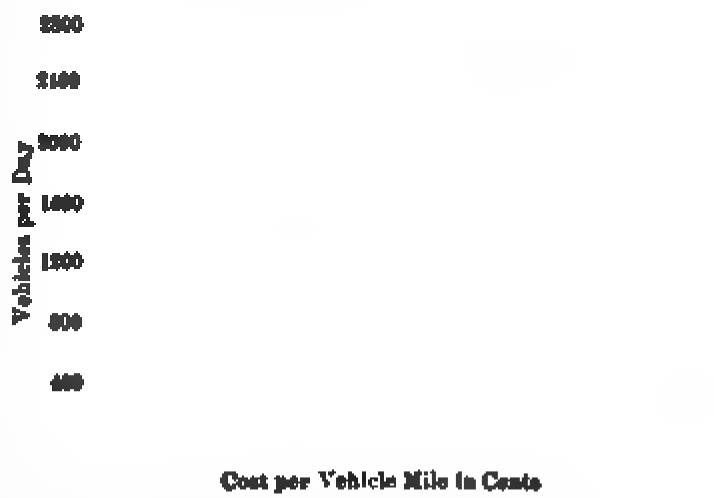

Fig. 4. Cost per Vehicle-Mile for Roads of Different Types

"The curves for the cost per vehicle-mile are discontinued at the points shown because experience has proved that in general the type would not be satisfactory beyond the traffic limits shown. Thus the limit of a 9-ft gravel road is 200 vehicles per day, that of a 16-ft gravel road, 500 vehicles per day, etc. In case a road should be constructed or is serving for a greater number of vehicles per day than the limits given, the maintenance would probably cost more than the values assumed. As the upper limit for concrete and brick is approached a 16-ft road would scarcely be able to care for the traffic, and it might be wise to build an 18-ft road at a slightly greater cost. Hence the upper portion of the curve for brick is dotted.

"**Curves Aid Selection of Road Types.** A number of interesting conclusions are apparent from a study of the curves. With the exception of concrete and brick, which cost nearly the same per vehicle-mile because of the probable longer life and lower maintenance cost of the latter, a type of road may be selected which may be expected

to serve for an appreciably lower cost than others within certain limits. Concrete, for example, should be able to carry the maximum of heavy travel in Michigan, say 2000 vehicles per day, at 0.20 cent per vehicle-mile. But if it were built for 200 vehicles per day, the cost to the county would be 2 cents for every vehicle that passed over the road. Evidently a 16-ft gravel road which would carry this traffic for one-half the cost would be far more economical.

"It is almost an established fact that untreated water-bound macadam will not stand up any better than gravel under a traffic that is composed largely of automobiles, and, as the curve shows, it is much more expensive. When constructed and maintained with a bituminous carpet, however, the life and the traffic limit are raised, and the cost is lowered. Thus treated, macadam forms an excellent intermediary between gravel and the higher types.

"It will be noted that when the traffic is near 200 vehicles per day, the cost of a 16-ft gravel road is about 0.30 cent higher than that of a 9-ft gravel road, but the necessity of providing for future increase would make it advisable to construct the former. Similarly, when the traffic is too heavy for gravel and it is necessary to construct surface treated macadam or concrete the latter being more often built, since the former has not yet attained a wide use in the state there is a great increase in the cost per vehicle-mile. It is desired of course to reduce this variation and keep the cost as low as possible.

"Costs Compared. Reference to the curves show that for the practical limit of a 16-ft gravel road, 500 vehicles per day, the cost per vehicle-mile is 0.40 cent, and that on a bituminous-surfaced macadam for 800 vehicles per day the cost is the same. The difference between the total annual costs given in the table is $466. Theoretically, therefore, if the traffic does not exceed 800 vehicles per day, $466 plus $150, the assumed maintenance for the gravel road below 500 vehicles per day, or about $600 per mile per year could be expended in the maintenance of the gravel road before it would be economical to build bituminous-surfaced macadam, provided that for that sum the road could be kept in a satisfactory condition. Practically, however, a gravel road carrying 800 vehicles per day would be in a continual state of repair and decidedly unsatisfactory.

"Depending on local conditions entirely, the gap between a gravel and a higher-class road may be bridged to a certain extent by paying more for the maintenance. When a county is financially able to build a better road for traffic in excess of 500 vehicles per day it should do so by all means. Without doubt future increase will in time make the road economically suited to the traffic passing over it."

METHODS OF COMPARISON

18. Classifications of Roads and Pavements Based on Traffic

In the light of the foregoing discussion and the general practice in both Europe and America it seems fair to conclude:

That earth roads, shaped up and kept in good condition, as well as sand-clay roads, while serving a good purpose where a community's financial condition or the traffic will not justify much expenditure, cannot be considered as improved road crusts.

That where there is light horse-drawn vehicle and small automobile traffic, water-bound macadam will be fairly successful, and a gravel road even will often be satisfactory.

That where the traffic consists of large touring automobiles in considerable numbers and large horse-drawn vehicles, a bituminous macadam should be used.

That where the automobile and vehicular traffic is heavy and interspersed with a considerable number of automobile trucks, a bituminous concrete road crust, or possibly concrete or brick, as governed by local conditions, will be most desirable.

That where the traffic consists of a large amount of motor trucks, large touring cars or motor-buses, as well as heavy horse-drawn vehicles, concrete or brick road crusts will be absolutely necessary from an economic standpoint, and often regular heavy traffic street pavements.

Assume, for instance, that a road will run from a sparsely settled section to a large and prosperous city. Beginning at the farther end the road will be simply of earth shaped up and kept in condition with wooden drags or other means, followed by a road crust of water-bound macadam, built possibly of local material, even if it be not capable of sustaining much wear. As the road approaches the city and receives increasing traffic, the water-bound macadam should receive a bituminous treatment, which in turn, as required, should be changed to bituminous concrete, Portland cement-concrete, brick, or other permanent material, and, in the vicinity of the city, to as substantial and permanent a street pavement as the particular traffic demands.

Table VIII.—Standards of American Road Builders' Association (5)

Materials	Maximum Traffic	Type	Remarks
Sand............	A1–B1–C1	Asphaltic oil, hot application Calcium Chloride	A temporary form of improvement, if sand is coarse and other durable material not available.
Gravel..........	A2–B2–C3–E1	Asphaltic oil, cold application.	Should have careful maintenance proportionate to traffic; using the log drag weekly—temporary.
Broken stone, soft	A2–B2–C2–D1–E1	Oil, paraffin base	Temporary treatment.
Broken stone, soft	A2–B2–C2–D1–E1	Asphaltic base, cold.	Treatment more lasting.
Broken stone, soft	A2–B2–C3–D1–E1	Asphaltic base, hot.	Treatment more lasting than preceding.
Broken stone, soft	A2–B2–C3–D1–E1	Tar, cold.	Treatment more lasting than preceding.
Gravel..........	A2–B2–C3–D1–E1	Bituminous penetration or mix.	Less constant maintenance required and more durable. Life of surface 5 to 10 years with reasonable care.
Broken stone, hard..........	A3–B3–C3–D2–E2	Bituminous concrete or penetration.	Subject to treatments given under Broken Stone, Soft, but with greater durability.
Concrete........	A2–B2–C3–D2	....	Usually dustless in open country requiring occasional sweeping or scraping in places.
Vitrified brick, stone setts and wood block....	A3–B3–C3–D3–E3	....	....

Table IX.—Classification of Traffic, American Road Builders' Association (5)

1. Horse-drawn, steel tires	A. Light vehicles.	(1) Light, up to 100. (2) Medium, 100 to 200. (3) Heavy, 200 up.
	B. Heavy vehicles, wagons, trucks.	(1) Light, to 75. (2) Medium, 75 to 150. (3) Heavy, 150 up.
2. Self-propelled, rubber tires	C. Passenger automobiles.	(1) Light, up to 100. (2) Medium, 100 to 400. (3) Heavy, 400 up.
	D. Motor-trucks and -buses.	(1) Light, up to 10. (2) Medium, 10 to 20. (3) Heavy, 20 up.
3. Self-propelled, steel tires.	E. Steam lorries and tractors.	(1) Light, 1. (2) Medium, 2 to 6. (3) Heavy, 6 up.

"Opinions of Canadian City Engineers (11a) concerning the suitability of various pavements as they have been used for different conditions of traffic, arranged in descending order of present popularity:

LIGHT RESIDENTIAL TO SEMI-BUSINESS: Sheet-asphalt, Bitulithic, asphaltic concrete, asphalt block, wood block, cement-concrete.

SEMI-BUSINESS TO MEDIUM HEAVY TRAFFIC: Bitulithic, sheet-asphalt, asphaltic concrete, wood block, asphalt block, cement-concrete.

HEAVY TRAFFIC: Brick, wood block, stone block, and scoria block.

ALONG STREET RAILWAY TRACKS: Wood block, brick.

QUIET STREETS: Wood block, Bitulithic, sheet-asphalt, asphaltic concrete.

GRADED STREETS: Brick."

The Mass. Highway Comm. and the engineers of Massachusetts are practically unanimously of the opinion:

"1. That some bituminous binder, either tar, asphaltic oil or asphalt, must be used on highways that have much motor vehicle traffic, to lay the dust and prevent the road from being destroyed, unless a pavement is used.

2. That some form of bituminous or cement-concrete roadway is the best surface to use on main roads where the traffic is not heavy enough to make a stone block, wood block, sheet-asphalt, or brick pavement on a concrete base necessary, or where money cannot be obtained to construct such a pavement.

3. That horses become accustomed to such surfaces and can be much helped by proper shoeing.

4. That separate roadways for motor vehicles and horse-drawn vehicles cannot be built within most of the present highway locations, and that the expense of constructing such roadways is absolutely prohibitive. That such separate roadways are only practical in parkways and possibly in a few cases in or near large cities."

Different Types of Pavements as Recommended by a Committee of Engineers for the Repaving of Boston (25). "CLASS 1. HEAVY TRAFFIC STREETS. Granite blocks laid on Portland cement-concrete base not less than 6 in in thickness, the joints to be filled with Portland cement-grout; in the case of excessive grades, tar pitch to be substituted for grout in the upper inch or so of the joints in order to provide better foothold for horses.

"CLASS 2. MAIN ARTERIES. The same type of pavement as Class 1, with a few exceptions where the surroundings require a smoother and less noisy surface, such as wood blocks or the best grades of bituminous pavements.

"CLASS 3. RETAIL SHOPPING AND OFFICE BUILDING DISTRICTS. Treated wood-block pavements, the best grades of bituminous pavements on a Portland cement-concrete base. At the present time the only wood recommended for wood-block pavements is long leaf yellow pine.

"CLASS 4. RESIDENTIAL DISTRICTS IN THE CITY PROPER. Treated wood-block pavements, the best grade of bituminous pavements or Portland cement-concrete pavements, the choice to be determined by the intensity and character of the traffic.

"CLASS 5. SUBURB AND RESIDENTIAL DISTRICTS. Cheaper types of bituminous pavements, using old macadam surfaces for the base where suitable, or Portland cement-concrete pavements.

"CLASS 6. PARK ROADS CARRYING ONLY PLEASURE TRAFFIC. Bituminous pavements, using old macadam for the base where suitable, or Portland cement-concrete pavements."

Peck, Street Commissioner of Hartford, Conn., (22) assigns the following values to maximum and minimum traffic for which each material is suitable, basing the traffic on the number of units per 24 hr and assuming a 1-horse vehicle as equivalent to 2 units:

Material	Maximum	Minimum
Wood Block	38 000	4000
Grouted Brick	25 000	2500
Sheet-Asphalt	18 000	2500
Bituminous Concrete	15 000	2500
Cement-Concrete	8 000	300
Bituminous Macadam	2 500	300
Water-bound Macadam	1 200	200

Brodie, while Borough Engineer and Surveyor of Blackpool, England, divided the streets within his district into five classes and determined the amount of traffic for which each class was suitable. Conclusions were as follows:

"CLASS No. 1. Foundation of Portland cement-concrete 7 in thick, covered with granite setts 5 in to 6 in in length, 3 in in width, and 6 in depth; jointed with fine, dry gravel and boiling pitch and creosote oil.

"This class is suitable for main suburban roads with traffic up to 200 000 tons per yd width of carriageway per annum; impervious to moisture; noisy, but clean; gradients up to 1 in 40.

"CLASS No. 2. Foundations of Portland cement-concrete 6 in in depth, covered by specially selected Karri or Jarrah blocks 6 in to 8 in length, 3 in in width, 4½ in in depth, laid close, direct on concrete, and grouted with boiling pitch and creosote oil.

"Suitable for first-class shop streets, with traffic of about 100 000 tons per yd width per annum; practically impervious, noiseless, clean, and dustless; gradients up to 1 in 40.

"CLASS No. 3. Foundations of hand-packed rubble 8 in in depth covered with 5 in, of tar-macadam.

"Suitable for residential streets having a light traffic of 20 000 tons per yd width per annum; impervious, noiseless, clean, and dustless; gradients up to 1 in 24.

"CLASS No. 4. Foundation similar to No. 3, but 7 in deep, with 2½-in gauge water-bound granite, to a finished depth of 5 in, blinded with fine granite chippings.

"Suitable for ordinary residential front streets with a light traffic of about 5000 tons per yd width per annum; pervious, comparatively noiseless, dusty, and sloppy; gradients up to 1 in 12.

"CLASS No. 5. Foundations similar to Nos. 3 and 4, 7 in in depth, covered with Haslingden setts, 6 to 8 in in length, 4 to 6 in in width, and 6 in in depth; jointed with dry gravel and boiling pitch and creosote oil; laid with a concave cross-section and channel in center.

"Suitable for back, or secondary access, streets 9 to 18 ft in width, with a traffic of 60 000 tons per yd width per annum; impervious, clean, and dustless; very noisy; gradients up to 1 in 12."

Opinion of British Engineers (28). Table X shows the preferences of engineers in various parts of England for different kinds of road crusts for different traffics, as given in the report of the British engineers to the 3d Int. Road Cong.:

Table X.—Opinions of British Engineers Relative to Adaptability of Different Types of Roads and Pavements

		Metalled Roads Bound with Tar, Pitch, Asphalt or Bitumen			Metalled Roads Water-bound
		Mixing or Grouting	Carpeting Methods	Other Methods	
	exceeding 60 000 tons.	refers grouting to mixing.	Has been successful with carpeting.	Surface tarring only useful for summer months.	Useful only for 3rd class roads having a traffic of 5000 tons per yd of width per annum and under.
Brodie, J. S., Blackpool......	Prefers granite setts for industrial centers where traffic is very heavy. Grit setts for secondary roads.			Spraying only useful for dry weather, and has same defects as carpeting.	
Brownbridge, Birkenhead......	Same opinion as Brodie, J. S.	Prefers this type for lighter traffic and side streets.	Approves carpeting methods.	Surface tarring useful and economical.	Useful on gradients, otherwise its use is rapidly diminishing.
Morgan, Bolton..........	Pre'ers granite setts for heavy traffic in industrial centers.	Does not like grout-			
Lancashire, Leeds	Agrees with above. Grit setts suitable for lighter traffic.				

BULL, Cheshire........	Considers granite setts preferable when water-bound macadam requires renewal under 4 years.	Tar concrete most economical for main roads carrying much motor traffic of light nature. Grouting unsatisfactory.			Suitable only for 2nd class roads subjected to very little motor traffic.
BURGESS, Middlesboro.....	Prefers granite setts for heavy traffic in industrial centers. Grit setts suitable for lighter traffic.	Approves of grouting from point of view of economy and traffic.			Considers this to be an out of date method except for district roads.
HADFIELD, Sheffield........	Prefers setts where annual cost exceeds 6d ($0.12) per sq yd.	Favors mixing methods and coatings 3½ in thick laid in grades, 2¼ in and 1¼ in, or 1½ in in three separate coatings.			Suitable for gradients too steep for tar concrete.
CARPENTER, West Riding.....	Same as Liverpool. Grit setts useful for gradients.	Favors these types from point of view of economy.			Suitable for steep gradients. Would not be tolerated if a cheap cinder were obtainable.
YABBICOM, Bristol........	Suitable for the heavy traffic of vehicles of cities. Most economical.	Considers bituminously bound material improvement over water-bound macadam.			
COL. CROMPTON...	Considers setts only suitable for dock sides and industrial centers.	Believes that for all traffic except the most intense, most acceptable to user and economical to maintain.	Roads having a good strong crust in fair order can be made satisfactorily for modern traffic at lowest cost.	Believes that tar pitch macadam with renewable sand and bitumen topping will be found acceptable to users from the point of economy.	Suitable where there is regular rainfall, no dust nuisance and where good stone is cheap.

19. Tabulations of Valuated Properties of Roads and Pavements

The properties which are possessed by a pavement, the assignment to each its proper percentage value, and the consideration of each pavement in relation to these different values were covered in Arts. 5 to 13 inc. It will now be possible to construct a table that will show in detail how each material stands relative to any other and also what proportion of the properties of a perfect pavement is possessed by each one under consideration. Table XI has thus been formed.

Table XI

	Percentage	Granite Block	Wood Block	Brick	Sheet-Asphalt	Bitulithic
Cheapness	14	8	8	13	14	12
Durability	21	21	16	12	15	15
Easiness of cleaning	15	10	14	15	14	14
Light resistance to traffic	15	13	14	15	11	12
Non-slipperiness	7	7	4	6	5	6
Ease of maintenance	10	10	8	6	6	6
Favorableness to travel	5	2	5	3	4	4
Sanitariness	13	9	13	10	12	12
Total	100	80	82	80	81	81
Less cheapness	....	72	74	67	67	69

It may be said that cheapness is not a physical characteristic, and that in discussing such characteristics of a pavement that item should be omitted. This is true to a certain extent, but as in all cities the cost must be taken into consideration, it has been indicated in the table. Eliminating this item, however, and making wood block, which has the highest value, the standard at 100, the values of the other pavements will be: Granite block, 97; Bitulithic, 93; brick, 91; sheet-asphalt, 91. It must be understood, of course, that this table is a very general one, that much of it is based on personal judgment, and that it will vary in different localities even if the conclusions are agreed to. The important point, however, is not that in this particular case each figure is correct, but that these principles must be studied and applied in considering paving materials. Understanding such principles, it will be possible for an engineer in any locality to construct a table in accordance with personal views and in accordance with local conditions.

The Use of Table XI can be illustrated in several ways. Assume, for instance, a street over which the traffic must be heavy and continuous. Ultimate cost is of great importance. It overrules first cost. Light resistance to traffic and foothold for horses are ruling elements, so that a given power may move its maximum load. The items first to be studied are, then: Durability, maintenance, traction, and the non-slippery property. Consulting the table and combining the values for these items, granite block has a value of 51, wood block 42, sheet-asphalt 37, brick 39, and Bitulithic 39. But when the figures are as close as the last three, ranging from 37 to 39, a careful examination of the remaining properties would be required. In this particular instance granite block ranks so high in the totals, and so far ahead in the general requisites, that it would seem that no mistake could be made in selecting it for the material to be used.

Consider next a residential street, built up with homes, whose owners have means sufficient to afford the best of anything they desire, and, while not wishing to be extravagant, do want and expect the best pavement that can be laid without regard to expense. This is an entirely different proposition. Cost, durability, and maintenance, so important before, can be left out of consideration altogether. Easiness of cleaning, non-slipperiness, favorableness to travel, and sanitariness are the governing characteristics. Working as before, granite block has 28, wood block 36, sheet-asphalt 35, brick 34, and Bitulithic 36. In this instance wood block and Bitulithic have the same values, according to the table, but sheet-asphalt is very close, so that the special qualities of each one should be considered before making a final decision. It may be said that durability and maintenance are too hastily disposed of, and that by considering them the results would be changed. But the basis of selection is that the property owners can afford the best. The problem is to select the best material under existing conditions. The above conclusions would generally hold good for the best retail streets.

Next consider a residence street with very light traffic, where the abutters wish a good but economical pavement, one that will be durable and as near the best that their financial condition will admit. This requires careful consideration. The destructive action of travel is almost wholly eliminated. Durability will be governed by the action of the elements. Every quality but slight resistance to traffic must be taken into account. This gives: Granite block 67, wood block 68, sheet-asphalt 70, brick 65, and Bitulithic 69. Sheet-asphalt leads Bitulithic by one point. It is, however, a somewhat cheaper pavement, and as its characteristics are practically the same, for the conditions specified, a property owner would, undoubtedly select it.

The above examples illustrate the use of the table, showing how it is possible to analyze the conditions that may arise in any case, and how easy it is to arrive at an intelligent and logical result when a systematic investigation is undertaken.

Crosby (13), in studying the different kinds of road crusts, gives values, as shown in Table XII, under the headings of V, W and X, when the figures under V are to be used on main country roads, such as state roads carrying fairly heavy mixed travel; those under W to be used on secondary country roads carrying moderate travel; and those under X to be used on minor country roads carrying farm travel almost wholly.

Table XII.—Showing the Values for Components of Ideal for Different Tables

Components	V	W	X
First cost, cheapness	15	15	15
Maintenance, cheapness	25	25	20
Durability	7	7	7
Ease of maintenance	8	10	10
Cleanliness	5	5	5
Low tractive resistance	10	5	5
Non-slipperiness	10	10	10
Sanitariness	5	5	5
Noiselessness	5	5	5
Acceptability	5	5	8
Favorableness to travel	5	8	10
	100	100	100

Values for four different road crusts for secondary country roads are shown in Table XIII.

Table XIII

Qualities	Values for				
	Ideal (W)	Brick	Plain Cement-Concrete	Bituminous Macadam	Water-bound Macadam
First cost	15	8	10	10	15
Maintenance cost	25	25	20	20	10
Durability	7	7	5	5	3
Ease of maintenance	10	7	8	8	10
Cleanliness	5	3	3	5	2
Low tractive resistance	5	5	4	4	4
Non-slipperiness	10	4	7	5	10
Sanitariness	5	4	4	5	3
Noiselessness	5	3	3	5	4
Acceptability	5	2	3	4	5
Favorableness to travel	8	3	5	6	8
	100	71	72	77	74

Blanchard (2) states that "the primary object of a detailed comparison of the relative merits of various roads and pavements is to enable the engineer to determine within certain limits the method of construction and, in some cases, the method of maintenance which are adaptable to local conditions from the standpoints of economy and efficiency. As an aid in comparison it is advisable to have at hand a table covering numerical values of certain factors which are susceptible to such form of comparison. Table XIV, which illustrates the treatment of the problem along these lines of investigation, gives assigned values for some of these characteristics of the different types of roads and pavements on the basis of ten for the value of the characteristic in an ideal pavement.

Table XIV

	Ideal Pavement	Sheet-Asphalt	Brick on Concrete	Stone Block on Concrete	Wood Block on Concrete	Cement-Concrete	Bituminous [illegible]		Bituminous Surface on Broken Stone	Broken Stone with Dust Palliative	Broken Stone	Gravel	Earth
First cost	10	8	5	1	1	6	7	7	8	9	9	9	10
Ease of traction	10	10	8	3	9	9	9	8	8	6	6	5	2
Non-slipperiness	10	4	8	7	4	6	7	7	7	8	10	10	10
Ease of cleaning	10	10	9	7	9	8	9	9	9	3	3	1	1
Noiselessness	10	7	6	3	9	6	9	9	9	10	10	10	10
Non-productive of dust	10	10	9	8	7	7	9	8	8	6	4	3	1

"It is necessary for each engineer to modify tabular information of this character in order that the values shall be based upon local conditions. For instance, it is obvious that the numerical values assigned to 'First Cost' will vary materially in different sections. It is likewise apparent that it is impracticable to blindly add up numerical values with the expectation that the type having the highest value is the pavement to be employed. In the great majority of cases one or more factors will also have a greater weight than certain other properties. Of course it is possible to weigh the

valuables of a table and then obtain totals for comparison. The totals obtained by the summation of numerical values of properties referred to in the above table must, however, be supplemented by values attributed to factors which are not covered in the table, due to their complex and variable character. As examples of such factors may be cited cost of maintenance, durability, etc, which properties are intimately related to local conditions pertaining to a given highway."

Table XV.—Forest Service, U. S. Dept. Agr., Valuations

Pavement Qualities	Percentage	Granite Block	Sheet-Asphalt	Brick	Macadam	Wood Block
Cheapness	14	4	6½	7	14	4½
Durability	20	20	10	12½	6	14
Ease of maintenance	10	9½	7½	8½	4½	9½
Ease of cleaning	14	10	14	12½	6	14
Low resistance to traffic	14	8½	14	12½	8	14
Non-slipperiness	7	5½	3½	5½	6½	4
Favorableness to travel	4	2½	4	3	3	3½
Acceptability	4	2	3½	2½	2½	4
Sanitary qualities	13	9	13	10½	4½	12½
	100	71	76	74½	55	80

Table XVI.—Canadian Engineers' Valuation of Different Pavements (11a)

Pavement	Percentage	Granite Block	Sandstone Block	Sheet-Asphalt
Cheapness, first cost	14	4.0	4.0	6.5
Durability	20	20.0	17.5	10.0
Ease of maintenance	10	9.5	10.0	7.5
Ease of cleaning	14	10.0	11.0	14.0
Low traction resistance	14	8.5	9.5	14.0
Freedom from slipperiness, average of conditions	7	5.5	7.0	3.5
Favorableness to travel*	4	2.5	3.5	4.0
Acceptability†	4	2.0	2.5	3.5
Sanitary quality	13	9.0	8.5	13.0
Totals	100	71.0	73.5	76.0

Pavement	Asphalt Block	Brick	Macadam	Creosoted Wood Block
Cheapness, first cost	6.5	7.0	14.0	4.5
Durability	14.0	12.5	6.0	14.0
Ease of maintenance	8.0	8.5	4.5	9.5
Ease of cleaning	14.0	12.5	6.0	14.0
Low traction resistance	13.5	12.5	8.0	14.0
Freedom from slipperiness, average of conditions	4.5	5.5	6.5	4.0
Favorableness to travel*	3.5	3.0	3.0	3.5
Acceptability†	3.5	2.5	2.5	4.0
Sanitary quality	12.0	10.5	4.5	12.5
Totals	79.5	74.5	55.0	80.5

*Favorableness to travel is dependent chiefly upon smoothness and freedom from dust and mud; secondarily upon the qualities composing ACCEPTABILITY.

†Acceptability includes noise, reflection of light, radiation of heat, emission of unpleasant odors, etc. It chiefly concerns the pedestrian and the adjoining resident."

Table XVII.—Adaptability of Roads and Pavements to Different Types of Streets and Traffic by Fixmer (16)

Kind of Pavement or W Surface		Kind of Foundation or Base	Kind of Filler in Joints	Estimated Life in Years	Note A Type of Streets Used on or Suitable for:	Note B Kind of Traffic Pavement is Suitable for:
5 in Granite block	2 in Sand	8 in Concrete	Tar	30	1-5-7	U-W-X
Modern granite block	1 in Mortar	6 in Concrete	Cement	(25)	1-3-5-9	V-W-X-Z

SECTION 25

SIDEWALKS, CURBS, GUTTERS AND HIGHWAY SIGNS

BY

MARK BROOKE

COLONEL, CORPS OF ENGINEERS, U. S. A.

SIDEWALKS

1. General Data Relative to Walks

A Sidewalk is a pavement designed solely for pedestrian traffic. The same qualities that go to make up a good pavement for vehicular traffic are necessary for sidewalks. Foot pavements are not subjected to such heavy loads as roadway pavements, but the destructive action of water and frost is the same in both cases and the various factors that enter into the construction of roadways must also be considered in the construction of a sidewalk.

The Essential Qualities of a good sidewalk are: Smoothness without slipperiness; non-absorption; durability; cleanliness; uniformity of wear; low first cost; ease of repair.

Materials generally used for sidewalks are cement-concrete, brick, stone flags, tar and asphaltic concrete, sheet-asphalt, asphaltic mastic, cinders, broken stone, gravel and wood planks. By far the greater proportion of sidewalk construction consists of cement-concrete, brick and flagging. Cement-concrete is rapidly displacing all other materials for sidewalk work.

The Width of sidewalks should be proportioned with reference to the volume of pedestrian traffic and the total width of the street. The general

practice is to make each sidewalk from 1/6 to 1/4 the total width of the street between property lines. On suburban streets, widths of from 4 to 6 ft are generally sufficient. For solidly built up residential streets, the walks should be from 8 to 12 ft and on important thorofares as much as 15 ft in width.

Location of Paved Sidewalk. On business streets the sidewalks generally extend from building line to curb. On residential streets it is usual to pave only a portion of the space between the curb and building line. The walk may be laid next to the building or adjacent to the curb. The latter location has the advantage that the unpaved parking back of the walk practically becomes part of the front yard and will be cared for by the householder. To provide for trees, unpaved pockets from 3 to 4 ft in width and from 5 to 8 ft in length should be left at suitable intervals along the curb, or a continuous unpaved strip may be left between the curb and sidewalk.

Relation of Sidewalks to Shade Trees (21). "The position of a sidewalk effects fundamentally the successful accomplishment of street tree planting. There are but three places where a walk may be placed: About the center of the allowed space, against the curb, or against the property. On account of a wide-spread ignorance of the importance of the matter, the general method is to place it directly in the center, or within 2 ft of the curb. A 60-ft street has a sidewalk space 12 ft in width, while a 50-ft street has one of 10. Allowing for a 5-ft flagstone, the space remaining for parking is 7 or 5 ft respectively. This space, if kept intact, provides sufficient room for the successful planting of any species of shade trees. If, however, the walk is put down in the center, the 7-ft and 5-ft spaces are split in two sections, both of which are inadequate for the proper growth of a good tree. The habit of placing walks in the center, therefore, allows a perfectly good strip of land between the curb and walk, or between the walk and property, to be wasted, and the custom should be abolished. There remains a choice between the two other locations, concerning which opinion is divided.

"The POSITION OF TREES must now be either inside or outside the walk. It is agreed that inside planting improves the appearance of the property, but adds little to the appearance of the street; that outside planting improves directly the street alone. The advocates of curb sidewalks and inside planting state the following advantages: The trees require no guards, and the roots have more room; the trees are out of danger from vehicles; it does away with the keeping up of the outside parking space; more moisture is supplied the young trees, and there is less injury inflicted by wires, leaking gas and sewer mains. Most of these claims are logical, but the street still shows a barren look, and an excessive width of paving without a break. Therefore, if the street is to be considered first, the proper position for the sidewalk is against the property, while the trees are placed near the outside line of the walk. The advantages of placing the sidewalk as far away from the curb as possible are as follows: The excessive expanse of bare asphalt is broken, thereby beautifying the street; pedestrians are not subject to being splashed by automobiles and trucks, the most serious indictment against curb-placed sidewalks; the shade trees hide, to a very great extent, the hideous poles lining the curb; the roots of trees are not so liable to injure the lawns of property holders by growing too close to the surface."

Slope. Sidewalks must have sufficient transverse slope to shed water quickly. Whenever practicable, the slope should be toward the curb. When necessary to slope away from the curb, a shallow gutter should be constructed at the back of the walk leading to sewer traps or cross-drains under the walk. The slope should be from 1/4 to 1/2 in per ft, depending on the smoothness of the surface of the walk. Cement-concrete walks should have a slope of about 1/4 in, flag and brick walks from 1/4 to 1/2 in per ft. Greater slopes than 1/2 in are noticeably uncomfortable and are apt to cause slipperiness.

Report, Com. Am. Soc. Mun. Imp. (9). "A slope of 1/4 in per ft from back to front of walk, dropping towards the curb, is recommended for the paving. A slope of 1 in per ft should be allowed the parkways to provide sufficient drainage from the walk."

"Sidewalk Steps (14a) are often necessary on steep-grade streets in hilly towns. As people walk faster out of doors, the steps should be considerably wider than those in buildings; and the writer advocates 15-in treads and 6-in risers. In one Minnesota town there is a long flight of steps with 40-in treads. Steps with 15-in treads, in series separated by landings, would have been better."

Park Walks. The same principles and methods of construction used for street walks should be applied to the construction of park walks. Being subjected to less severe usage by traffic but to greater exposure to the action of water, they are usually made of lighter construction and provided with better drainage facilities than street walks. Park walks are usually built with a crown of from ¼ to ½ in per ft to shed the water to both sides, and are lined on one or both sides with shallow gutters of brick or small cobbles. Cement-concrete, asphalt tiles and gravel are the materials most commonly used in their construction. Cement-concrete, on account of its stiff and artificial appearance, is generally limited in use to the walks of heaviest traffic.

Table I.—Character and Cost of Sidewalks in 1915 in Several Cities

From *Municipal Journal*, Feb. 3, 1916

City	Material	Thickness in Inches	Sq Yd	Price per Sq Yd
San Francisco, Cal.	Broken stone	...	10 812	$0.59
Denver, Colo.	Cement-concrete	4	119 060	0.95

Bennington, Vt.	Tar concrete	...	397	0.75
Port Townsend, Wash.	Wood	...	524	0.56

2. Cement-Concrete Walks

Cement-concrete sidewalks, also termed granolithic and cement walks, more nearly meet the requirements of a good walk than any other type of sidewalk construction. While requiring some skill and careful attention to details in construction, they are of moderate cost and, when properly laid, are smooth, durable and attractive in appearance. They possess the further advantage that the materials for their construction and repair are readily available in practically all localities.

A Granolithic Walk is one in which the aggregate of the mortar wearing surface is composed in whole or part of stone screenings.

The Essential Features in the construction of a cement-concrete walk are: A firm, but porous foundation; a base of well made, strong cement-concrete; a wearing coat of rich mortar finished to a smooth dense surface and the division of the walks into blocks with lines of weakness between them along which all cracks will occur.

The Foundation or frost base is designed primarily as a means for disposing of water which would otherwise accumulate under the walk and result in its being moved by frost. When drainage of the natural soil is good, no base is necessary. In soil where the base and natural drainage can not take care of the water, drains of stone or tile leading into available sewers should be provided to prevent the accumulation of water in the base. In grading for the foundation all loose or spongy places should be cut out and their place filled with suitable material. The subgrade should be trimmed to a transverse slope of about ½ in per ft and well compacted by ramming or rolling. Fills should be made in layers not over 6 in in thickness and well consolidated. The fill should be carried at least 1 ft beyond the edge of the walk to protect the foundation from being undermined by wash.

MATERIALS generally used for foundations are sand, broken stone, brick, gravel or cinders, the latter being the most common. Only steam or black cinders should be used; household ashes are not suitable.

The DEPTH of foundations varies from 3 to 12 in. As a rule a depth of 6 in is sufficient. The foundation should be thoroly compacted by tamping or rolling. Cinders should be wetted to assist in consolidation. The finished surface of the foundation should be parallel to the top of the walk.

Cement-Concrete. The concrete base is generally made from 3 to 4 in thick. A thickness of 4 in is recommended. Proportions of 1 : 3 : 6, 1 : 2½ : 5, 1 : 2 : 5, and 1 : 2 : 4 are commonly used. Proportions of about 1 : 2 : 5 are recommended. Excerpts from the 1912 specifications of the Assn. Standardizing Paving Specifications follow:

"**The Fine Aggregate** shall consist of any material of silicious, granitic, or igneous origin, free from mica in excess of 5%, and other impurities, and shall be of graded sizes ranging from ¼-in down to that which shall be retained on a 100-mesh sieve, not more than 20% of which will pass a 50-mesh sieve for the base; and from ¼-in down to that which will be retained on a 80-mesh sieve, nor more than 20% of which shall pass a 50-mesh sieve for the top or wearing surface.

"**The Coarse Aggregate** shall be sound gravel, broken stone or slag having a specific gravity of not less than 2.6. It shall be free from foreign matter, uniformly graded and of sizes that will pass a 1-in screen and be retained on a ¼-in screen.

"**In Preparing the Concrete for the Base**, the cement and aggregate shall be measured separately, and then mixed in such proportions that the resulting concrete shall contain fine aggregate amounting to one-half of the volume of the coarse aggregate; and that 5½ cu ft of concrete in place contain 94 lb of cement. The top or wearing surface shall be composed of 1 part Portland cement and 2 parts fine aggregate, mixed with sufficient water to produce a mortar of a consistency which will not require tamping, and which can be easily spread into position with a straight-edge."

Forms. The concrete is laid between side forms, usually made of wood. The upper edges of the forms should be in the plane of the top surface of the walk and the forms should be securely staked so as to hold to line and grade. When the walk abuts a curb which is on line and grade, the curb may be utilized as a form. If the walk is laid solid from curb to building, a narrow strip should be placed against the curb, to form an expansion joint.

Placing the Concrete. As soon as the concrete is laid between the forms, it should be thoroly tamped and the surface made exactly parallel to the top of the walk and at a depth below it equal to the thickness of the mortar

wearing course. The concrete should be wet enough to tamp without causing a film of cement to flush to the surface. The surface of the concrete base should be left rough so as to get a good bond with the mortar topping. If the foundation is dry and especially if it consists of cinders, it is well to wet it throroly before laying the base in order to prevent the absorption of water needed by the concrete.

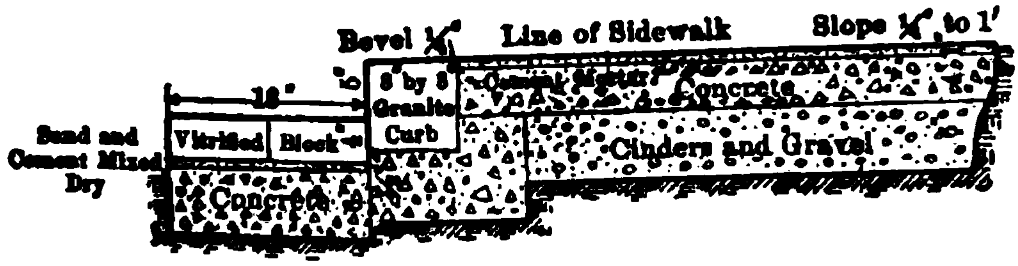

Fig. 1. Cement-Concrete Sidewalk, and 8 by 8 in Curb and Brick Gutter on Concrete Base

The Wearing Course consists of a rich mortar of cement, sand, granite, or trap screenings or a mixture of sand and screenings. Proportions of 1 : 1, 1 : 1½, and 1 : 2 are generally used. The 1912 specifications of the Assn. Standardizing Paving Specifications are as follows:

"The top or wearing surface shall be composed of 1 part Portland cement and 2 parts fine aggregate mixed with sufficient water to produce a mortar of a consistency which will not require tamping and which can be easily spread into position with a straight edge."

While a rich mortar is essential, an excess of cement is liable to cause crumbling or scaling of the surface. Screenings make a more durable surface than sand and one more nearly resembling natural stone. Sand is cheaper and if of good quality is satisfactory for ordinary conditions. Special care must be taken to keep the aggregate free from mud lumps, dirt, chips and leaves which will cause the formation of unsightly and injurious pits in the surface that can not be repaired.

The THICKNESS of the top course varies from ½ to 1 in. One inch is recommended for standard construction. The fresh mortar should be spread on the concrete base before the latter reaches its initial set, worked to grade with a straight-edge and beaten and worked with wooden floats so as to produce as dense a mortar as possible. The surface should be finished with toothed roller, wire brush or trowel as desired. The trowel surface while harder is not so pleasing on account of its glaze. Care must be exercised that the mortar is not so wet as to delay the finishing, as very wet mortar can not be floated and finished. The mortar should be of such consistency that it can be easily worked with a straight edge. An excess of water may be removed by working into the mortar a mixture of dry sand and cement of the same proportions as the mortar. Neat cement should not be used to take up excess water.

Concrete walks are always divided into blocks or slabs, usually square, containing from 9 to 36 sq ft. Small blocks are preferable to large blocks, as they are less liable to crack and are more easily repaired. With small blocks, cuts for trenches or repairs can be made along the joints thus enabling a neater repair to be made.

Joints should be continuous both longitudinally and transversally. Various methods of making the block divisions are used. One method is to construct wooden or metal forms the size of the blocks and lay and finish each block separately. Another method is to lay the base in separate blocks divided by narrow forms which are immediately withdrawn and the joints filled with sand. The top is then laid monolithic and joints cut in the top over those in the base. The following method, which is the cheapest and gives good results if carefully done, is coming into general

use: The base is laid monolithic between the side forms and divided into blocks by the use of a broad bladed tool cutting entirely thru the concrete, and the joints thus formed are filled with sand. The top is then laid as a monolith and joints cut in it exactly over the joints of the base. The location of the joints is accurately marked on the side forms and on transverse strips nailed to them, and the cutting tool is guided by a straight-edge. This method is especially adapted when gravel concrete is used for the base, as there is less tendency to fracture the concrete than in the case where the cutting tool has to displace a sharp angular aggregate. If the joints are not cut entirely thru the top course, there will be less liability of water entering the base. Furthermore the partially cut joint provides a plane of weakness along which fracture will occur in case of settlement or contraction.

Expansion Joints should be provided where necessary. It is usual to specify joints about every 50 ft. By the exercise of judgment this interval can be increased, and as such joints are always objectionable in a walk their number should be kept at the minimum needed to prevent damage to the walk or abutting curb from excessive expansion. Local conditions of temperature, the amount of exposure or shade, and probably the conditions of temperature and weather, at and immediately subsequent to the laying, affect the amount of expansion or contraction. Joints should be provided where the walk abuts a curb at a street or alley return. Expansion joints are formed by a thin plank which should be withdrawn after the concrete has set and the joint filled with sand or a bituminous filler. Insufficient provision for expansion is generally manifested by pushing out the curb at corners or by buckling at a joint. In such case the walk will not contract to its original position and on the other hand if it is cut off and the curb reset no further buckling or damage to the curb will occur from expansion.

Coloring Matter is usually added to the surface to reduce the unpleasant glare of the natural color of new concrete. Lampblack is generally used for the purpose. Proportions of from 2 to 16 lb per barrel of cement will produce colors varying from light slate to dark bluish slate. If it is desired to have the color permanent, the coloring matter should be incorporated in the entire wearing course by mixing it with the dry cement and fine aggregate before making the mortar. A common method is to add the coloring matter to a mixture of dry sand and cement of the same proportions as used in the wearing course. This mixture is sprinkled over the wearing course after it is in place and then floated and troweled into the surface, repeating the operation until the desired shade is obtained. Tho the color applied in this way will gradually wash out, by the time it has disappeared the walk will have become darkened from usage. When new blocks are laid in repairing a walk they should be made slightly darker than the walk to allow for bleaching. Neat coloring matter should never be applied to the surface as it will cause flaking. Different colors can be produced by use of proper coloring matter. Table II of colors and proportions is given by L. C. Sabin.

At Alley and Driveway Crossings the wearing surface should be finished, with a groover, in blocks about 4 in square, both for a foothold for horses and to attract the attention of pedestrians. Crossings for heavy traffic should be laid with vitrified or granite block. Driveway and alley pavements should be laid flush with the top of the sidewalk to a point near the curb, in order not to introduce a step in the line of the walk.

Protection of Green Concrete. Precautions must be taken to prevent the fresh surface from being pitted by rain. When completed, the walk should be be kept moist and protected from traffic and the elements for at least 3 days.

Freezing. On account of the exposed location and small mass of concrete in this class of work it is particularly liable to injury when laid in freezing weather and special precautions should be taken in mixing and laying under such conditions.

Single-Course Walks. Concrete walks are sometimes constructed as one-course work. A richer and wetter mixture should be used than for two-course work, the best proportions being about 1 : 2 : 3. Slab divisions should be made as in the case of two-course work. The concrete should be well tamped, struck off and smoothed even with the top of the form. The coarser particles of the aggregate should then be tamped into the surface, with a form of tamper designed for the purpose, a sufficient depth to permit the walk to be finished as in the case of two-course work.

Table II.—Colored Mortars

Colors Given to Portland Cement Mortars Containing Two Parts River Sand to One Cement

Dry Material Used	Weight of Dry Coloring Matter to 100 Lb Cement				Cost, in Cents of Coloring Matter per Pound
	½ Lb	1 Lb	2 Lb	4 Lb	
Lamp black..	Light slate..	Light gray...	Blue gray...	Dark blue slate......	15
Prussian blue	Light green slate......	Light blue.. slate......	Blue slate..	Bright blue slate......	50
Ultramarine blue......	....	Light blue slate......	Blue slate...	Bright blue slate......	20
Yellow ochre	Light green	....	....	Light buff..	3
Burnt umber	Light pinkish slate.......	Pinkish slate	Dull lavender pink...	Chocolate...	10
Venetian red	Slate, pink tinge......	Bright pinkish slate...	Light dull pink......	Dull pink...	2½
Chattanooga iron ore...	Light pinkish slate.......	Dull pink...	Light terra cotta.....	Light brick red.......	2
Red iron ore.	Pinkish slate	Dull pink...	Terra cotta..	Light brick red.......	2½

Failures of cement-concrete walks, assuming good materials in proper proportions are used, can generally be ascribed to one or more of the following causes: Poor drainage of foundation; inadequate provision for expansion and contraction; lack of bond between the concrete base and mortar top and imperfect jointing between slabs. Strict attention to all details in the execution of the work is essential to prevent failure from these and other causes.

Vault Work. Concrete, in the form of plain or reinforced slab construction, is particularly adapted for sidewalk work over vaults. This class of work, involving as it does special features of design and construction, is more properly a subject of building construction.

Cement-Concrete Plates as Laid in Germany (22). "Square concrete plates laid so that the diagonal of the square is at right angles to the direction of the walk is an

arrangement much used, with a border of plates in the shape of bishop's caps. Another arrangement noticed was the use of oblong and square plates laid so as to break joints. The squares are either 12½, 16½ or 20 in, depending on the width of walk desired, and the oblong plates 16½ by 25 in. The thickness of these plates is about 2 in. They are made of cement, sand and fine crushed stone-granite, basalt or diabase and are manufactured in machines under high pressure."

The Specifications of Pittsburgh are, in part, as follows:

"Concrete sidewalks shall consist of a foundation of gravel or broken stone 5 in in depth, and a slab of Portland cement-concrete 5 in in depth. The sidewalks shall be laid in general with a slope of ¼ in per ft from the curb line to the building line.

"The Foundation Course shall be 5 in and shall consist of clean gravel or broken stone which shall be free from dust, dirt or other foreign matter. The material shall range in sizes from 2½ to ⅜ in. The foundation course shall be thoroly rammed or rolled and then leveled off so as to be paralleled with the finished surface of the sidewalk. Cinder or clinker where used for foundation, shall be of acceptable material approved by the Director, of the sizes hereinabove specified for gravel or broken stone and shall be free from dust, fine ash or other objectionable or foreign matter.

"Cross-Drains. When the sidewalk pavement does not extend to the curb, cross-drains 10 in by 12 in in section shall be provided at intervals of 25 ft so as to connect the foundation of the sidewalk with the broken stone curb drain. These cross-drains shall be filled with stone or gravel which will pass a 3-in screen.

"The Concrete Masonry in the sidewalk shall be 5 in in thickness. The concrete shall be mixed in the proportions of 1 volume of cement, 2 volumes of sand and 4 volumes of gravel or broken stone. The gravel or broken stone shall be uniformly graded from fine to coarse and shall all pass a 1¼-in screen and be retained on a ¼-in screen. The sand shall preferably be coarse and in no case shall more than 3% of the same pass a 100-mesh sieve. Sufficient water shall be added so as to produce concrete of a consistency which can be readily worked and finished in a manner hereafter required. The sidewalk slabs shall not be more than 6 ft in length, nor shall they contain more than 36 sq ft of surface area. After mixing, the concrete shall be handled rapidly and each slab finished in one continuous operation. The concrete shall be deposited between cross-forms, forming slabs of the dimensions hereinbefore required, and shall be properly tamped against the forms. The coarse material in the concrete shall be forced down with a special tamper and the surface of the sidewalks shall then be struck off by means of a strike-off board which shall be moved along the side forms. Care shall be exercised to prevent the accumulation of coarse material in front of the strike-off board, and to insure the placing of good dense concrete thruout the slab. The cross-forms shall be withdrawn when the concreting of the next slab is commenced, the location of the joints being marked on the side forms. The surface shall be finished with a wooden float, care being taken to thoroly compact the concrete and the wearing surface, when finished, shall have a moderately rough surface. On steep grades the surface shall be roughened, as ordered by the Director in the field. Working with a steel trowel is expressly prohibited. After the concrete has set sufficiently, the slab divisions shall be cut the entire depth of the concrete and the joints filled with dry sand. All edges of the slab shall be finished to a radius of about ⅜ in. The application of cement to hasten hardening is prohibited. Excess water shall be removed with a rag or mop. The contractor may, if he so elects, lay the sidewalk in alternate blocks.

"An Expansion Joint ⅜ in in width shall be provided every 50 ft, but in all cases an expansion joint shall be placed at each end of each section of walk. The expansion joints shall extend the full width of the sidewalk and the full depth of the slab and shall be filled either with bituminous joint filler conforming to requirements, or a suitable and approved strip filler.

"After the pavement is completed the contractor shall use suitable means to prevent damage to the finished surface and shall keep it moistened with water for at least 4 days."

St. Louis Specifications for Expansion Joints at Curbs are as follows: "Where the sidewalk pavement will touch curbs at street intersections or paved alley aprons, the bottom course of concrete and the wearing surface shall be separated from the curb or the alley pavement by a layer of pre-molded expansion joint material which shall fulfill the following specifications: Expansion joints shall be composed of asphalt or pitch in combination with either fiber or with a fine mineral aggregate. If a mineral

aggregate is used, none of the particles shall be of such size as to be retained on an 80-mesh sieve. The joints shall be pre-molded in the form of a board ⅛ in thick, and of a width equal to the entire depth of the granitoid pavement. The consistency of the mixture in the completed joint shall be in accordance with that of the sample on file in the Office of the President of the Board of Public Service. Joints shall be made up in strips not less than 2 ft in length, and shall not vary appreciably from the specified thickness of ⅛ in. This joint shall extend to the full depth of the bottom course of the sidewalk pavement, and should the concrete foundation of the curb or alley pavement be at or above the bottom of the concrete base of the sidewalk pavement, it shall be picked down to below that level, and shall be separated by a layer of tar-paper or other material satisfactory to the Engineer."

Cost Data. The cost of cement-concrete walks, including excavation for the depth of the walk and gravel or cinder foundation, varies from about $0.80 to $1.50 per sq yd (see Table I, Art. 1). The details of cost to the contractor in Webb City, Mo., of constructing a two-course cement-concrete walk, not including cinder base, follows (29): The first course was 1 : 3 : 5 concrete, 3¼ in thick; the wearing course was 1 : 1½ mortar, ¾ in thick.

Labor and Materials for 9567 Sq Ft

" Labor:	Cost per Sq Ft
1 foreman, 54½ hr at $0.666	$0.0038
1 finisher, 68½ hr at $0.444	0.0080
2 mixing mortar, 104 hr at $0.222	0.0024
2 feeding mixer, 109 hr at $0.222	0.0025
2 wheeling mortar and concrete, 125 hr at $0.222	0.0029
2 placing concrete and mortar, 119 hr at $0.222	0.0028
Total for labor	$0.0174
Material:	
Cement, concrete and mortar, 748 sacks at $0.40	$0.0313
Sand, mortar, 467 cu ft at $0.08	0.0039
Gravel, concrete, 97 cu yd at $0.50	0.0051
Total for material	$0.0403
Total for labor and material	0.0577 "

3. Brick Walks

Brick sidewalks are generally constructed of building brick. While vitrified paving or sewer brick are better, their cost prevents their use except in cases where architectural or traffic considerations call for a special treatment. Building brick for sidewalks should be a hard burned dark red brick, as far as practicable of uniform hardness and size, as a variation in hardness causes uneven wear, while uniformity in size greatly reduces the labor of laying.

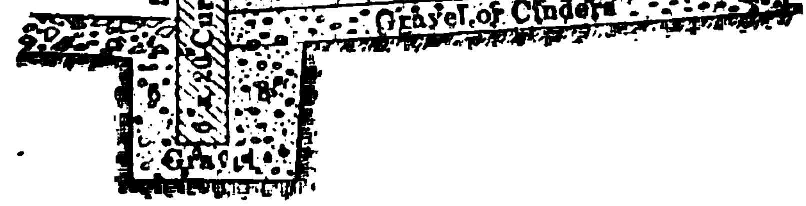

Fig. 2. Brick Sidewalk and 6 by 20-in Curb on Gravel Base

Construction. A foundation of gravel or cinders about 6 in in thickness should be provided for the walk. The work of preparing the subgrade and constructing the foundation should be similar to that for a cement-concrete walk and the same degree of care used (see Art. 2). The bricks should be bedded in a 2-in layer of clean sand spread over the foundation and brought exactly parallel to the surface of the finished walk. The bricks should be laid on their side by pavers kneeling on boards on the part of the walk already laid. The bricks may be laid either at right angles

to the line of the walk (see Fig. 3) and so as to break longitudinal joints, or in herring-bone pattern (see Fig. 4). A herring-bone walk has a more finished appearance and will hold a more even surface than the rectangular walk. It requires greater care in laying and more labor and material for cutting and is consequently slightly more expensive. When the walk does not abut a curb or coping, it should be protected by a course of brick laid on edge. A light covering of fine dry sand should be spread over the walk as soon as the bricks are laid and the bricks brought to a firm bearing by placing a plank over several courses and ramming with a heavy rammer. After the ramming is completed the walk should be covered with about ¼ in of fine sand which should be broomed into the joints. Any excess sand should be allowed to remain to be worked into the joints by rain and traffic. In dry windy weather this sand should be sprinkled to prevent its loss and the annoyance due to the blowing sand. Driveway and alley crossings should be paved with the brick laid on edge and if the traffic across the sidewalk is heavy, vitrified paving brick with grouted joints should be used.

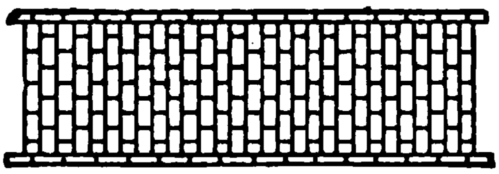

Fig. 3. Brick Sidewalk, Rectangular Pattern

Boston Specifications are as follows: "The bricks to be used are to be burned hard entirely thru, straight-edged, of compact texture and regular and uniform in shape and size; bricks which after being thoroly dry and then immersed in water for 24 hr absorb more than 8% of their volume in water may be rejected; any edge of the brick sidewalk not against a curb or building is to be supported by a continuous spruce plank 2 by 8 in, firmly set in the ground on edge, and held in position by spruce stakes 2 by 4 in, of sufficient length to make a firm and lasting support; suitable areas around trees are to be left unpaved, as directed by the Commissioner. After the roadway is laid and rammed as hereinbefore provided, the sidewalk is to be laid. The subgrade for the sidewalks, where the brick sidewalks are to be laid, is to be 8 in below and parallel with the surface of the finished sidewalk, and on this subgrade the foundation is to be made consisting of coarse-screened paving gravel, no stone larger than ¾ in in greatest dimension being used, and this gravel is to be thoroly compacted by rolling or ramming so that it will be 4 in thick when completed. Upon this foundation is to be spread a layer at least 2 in thick of clean, sharp sand, special care being taken to make the surface of the layer parallel with the finished sidewalk, and the layer of sufficient thickness to bring the bricks to the grade and slope required when rammed firm, as hereinafter provided, and on this sand the bricks are to be laid on their widest side, in courses of uniform width and depth, at right angles with the street, or in herring-bone fashion, with close joints, all longitudinal joints broken by a lap of at least 2 in; the bricks are to be then covered with clean, fine, dry sand, screened thru a 20-mesh sieve; and upon the bricks a plank, covering several courses, is to be placed and carefully rammed with a heavy rammer until the bricks reach a firm, unyielding bed and present a surface of the proper grade and slope, and any lack therein is to be corrected by taking up and relaying the bricks; after the ramming, a sufficient amount of fine, dry sand, aforesaid, is to be spread over the surface and thoroly swept or raked so as to fill the joints."

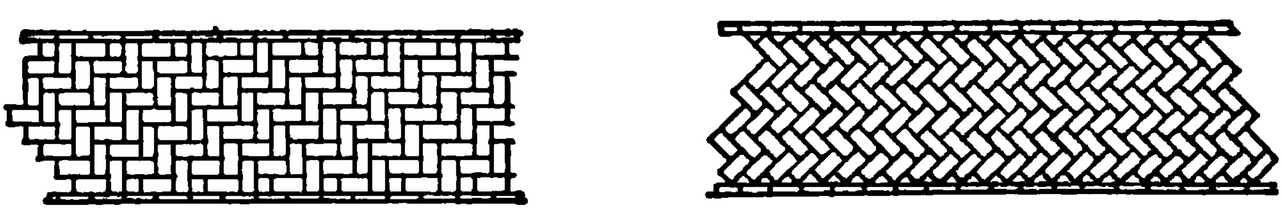

Fig. 4. Brick Sidewalk, Herring-Bone Patterns

Cost Data. Bricks suitable for sidewalks cost from $8 to $10 per M, and will lay flat about 35 to the sq yd. A paver can lay about 75 sq yd

per 8 hr day of square course walk. The cost of a walk as described above is about $0.70 per sq yd divided as follows:

Loading and hauling gravel or cinder base not exceeding 1 mile	$0.06	
Placing and tamping foundation	0.04	
Loading and hauling paving bed not exceeding 1 mile	0.01	
Placing and striking paving bed	0.02	
Laying and ramming brick and spreading sand covering	0.06	
Total cost of labor per sq yd	$0.19	$0.19
35 brick at $10 per M	0.35	
1/6 cu yd cinders at 60 cents	0.10	
1/15 cu yd sand at 90 cents	0.06	
Total cost of material per sq yd	$0.51	0.51
Total cost of labor and material per sq yd		$0.70

For additional cost data, see Table I, Art. 1.

Clay Tile have been used to some extent for sidewalks. The tile are made in square and hexagonal form about 2 in thick and from 8 to 12 in square. The construction of tile walks and method of laying the tile are the same as described for brick walks.

4. Stone Walks

Stone flagging is a very common material for sidewalks on business streets and also on residence streets in those localities where a suitable stone is available. Granite and sandstone are generally used, especially the variety of sandstone known as bluestone. The crystalline varieties of sandstone, such as the Medina and Colorado stone, are also used, tho they are not so suitable as bluestone.

Granite. On account of the cost of dressing, transporting and handling granite, its use has been limited to business streets of heavy traffic, or where large blocks are required to span vaults under the walk. Reinforced concrete has very largely taken its place for this latter class of work. Granite slabs, while practically indestructible, require occasional roughening to prevent the surface from wearing slippery. The slabs are usually from 4 to 6 in thick, and of widely varying sizes.

Bluestone makes an excellent sidewalk paving material. It splits readily into flags of the desired thickness, with even faces, requiring but little dressing. It is compact in texture, hard enough to withstand abrasion, and wears fairly smooth without becoming slippery. Bluestone flags should be from 10 to 20 sq ft in area and from 2 to 4 in thick. They should be laid in a bed of sand about 3 in thick overlying a foundation of gravel or cinders similar to that for brick walks. When the subgrade is of suitable material and well drained, the foundation may be omitted. The edges should be cut straight and square and smooth enough to lay thin joints. The stones should be laid with their length across the walk and should break joints longitudinally. The joints should be closed with a lean cement mortar.

Pittsburgh Specifications for Flagstone Walks are, in part, as follows:

"Flagstone sidewalks shall consist of a gravel or cinder foundation 4 in in depth, a sand cushion 3 in in depth and a flagstone wearing surface 3 in in thickness, making the total thickness of the completed pavement at least 10 in.

"The Foundation shall be of cinder or gravel, free from foreign matter and must contain sufficient fine material to fill the voids in the coarse material. Where the

sidewalk does not adjoin the curb, cross-drains of broken stone 10 by 12 in in cross-sections shall be provided at intervals of 25 ft, connecting the sidewalk foundation with the broken stone curb drain. The sand cushion shall consist of clean Alleghany River sand.

"Wearing Course. The flagstone shall be of the best quality of gray Cleveland sandstone or stone equal in quality thereto, of uniform color and free from flaws or defects of any kind. Unless otherwise specified the flags shall have a width equal to the width of the pavement, a length of not less than 4 ft and a thickness of at least 3 in. The surface shall be sawed to a plane, free from warps, depressions or projections. The edges shall be pitched to true lines and squared for the full depth of stones. The joints shall be cut to straight surfaces and at right angles with the line and surface of the walk, for the full width and thickness of the stone. The flags shall be set with close joints and with a firm bearing thruout their entire area on the cushion and brought to the required grade and cross-section. Where ordered, the top and edge of the flags shall be trimmed and trued after the flags are laid.

Cost Data. The cost varies within wide limits, depending largely upon the cost of transportation (see Table I, Art. 1). In New York City, flag walks of North River bluestone cost from $1.66 to $2.20 per sq yd laid; and in Boston from $2.50 to $3.00 per sq yd.

Small Stone Blocks as Laid in Germany (28). "The mosaic walks are made from small cut stones of from 1½ to 2½ in surface dimensions, laid in semi-circles on a sand cushion, with a cinder base, and tamped smooth, the joints being filled with sand. By using dark and light colored stones very pretty contrasts are obtained as well as a comfortable walk. This pavement is used very often as a border to concrete plates."

5. Bituminous Walks

Tar Concrete is used to some extent in New England, and for suburban sidewalks in localities where a cheap tar is available. The walk is usually constructed in two courses, a foundation course about 4 in thick of coarse gravel thoroly coated with tar, and a wearing course about 1 in thick composed of a mixture of coarse sand and tar, each course being tamped and rolled as it is laid. An intermediate or binder course of smaller gravel is sometimes used. It is difficult to maintain a satisfactory surface on tar walks and they should be considered only a temporary construction. Their cost is about $0.60 per sq yd (see Table I, Art. 1).

In Newton, Mass., a Three-Course Method is used, the different courses being described as foundation course, binding course, and wearing course. The foundation course is composed of coarse gravel from 2 to 4 in in greatest diameter, thoroly coated with hot tar. The binding course is composed of clean screened gravel not exceeding 1 in in greatest diameter, which is heated and mixed with a hot coal tar composition in an amount of about 1 gal of the tar to 1 cu ft of gravel. The wearing course is composed of screened sharp sand, which is heated and mixed with a coal-tar composition, the mixture consisting of not more than 75% of sand and not less than 25% of the tar, by weight. The surface is laid to a total depth of 3 in. Each course as it is laid is thoroly tamped and rolled. The binding course fills the voids in the foundation course to a large extent. The total thickness of these two courses, after compaction, is not less than 2¼ in. The wearing course, which is ¾ in thick, is laid and rolled in a similar manner. The top surface, which is usually sprinkled with a fine sand or Portland cement, is well rolled.

Characteristics. Tar-concrete sidewalks usually are not slippery. If the tar is of the proper consistency the surface is rather elastic and pleasant to walk upon. The use of a tar not possessing the proper characteristics may result in cracks being formed in the surface in cold weather, with consequent disintegration of the pavement, or in warm weather the tar compound may soften to such an extent that the surface becomes objectionable to walk upon. The surface is easily cleaned when intact and is also one which may be easily repaired. Its low cost has led to its general use in many places, altho at the present time it is being replaced to a considerable extent by cement-concrete.

Asphalt Tile Walks. The manufacture of compressed asphalt tiles was begun about 1886. Substantially the same methods are used as have proved successful in the manufacture of asphalt blocks for street pavements. In the manufacture of asphalt tiles, however, a selected white limestone is used for the mineral aggregate, instead of crushed trap rock, as used in the street blocks. The particles of crushed limestone stand out in marked contrast to the black asphaltic cement, giving the tiles an attractive appearance. As the tiles are intended for use in places subjected to foot traffic only, the limestone rock is abundantly durable for the purpose. The crushed limestone and asphaltic cement are thoroly mixed while hot, and these materials are then pressed into block form, receiving a compression of over 100 tons on each tile. This method produces a tile of great density, free from voids, and non-absorbent. Tiles have been used in private work in a multitude of places and under many varying conditions. The Department of Parks of New York City commenced using tiles in 1888. In Prospect Park alone, about 700 000 sq ft of tile walks were laid between 1888 and 1911.

Dimensions of Tiles and Method of Construction. The tiles are made in the following sizes and shapes: Square tiles 8 by 8 by 2 in deep, hexagonal tiles 8 in on the short diameter by 2 in deep, and small hexagonal tiles 5¼ in on the short diameter by 1 in deep. The large hexagonal and square tiles are usually laid upon a foundation of 6 to 8 in of gravel and sand, with a curbing or border of square tiles set on edge. These tiles have a very large bearing surface and do not require a concrete foundation for stability. The small hexagonal tiles, 1 in in thickness, are designed to be laid on a foundation of 3 in of concrete and ½ in of mortar, or upon a mortar bed spread upon a broken stone or gravel foundation.

Asphalt Mastic. This type of pavement is constructed in France by preparing a mastic from a combination of rock asphalt and a refined asphalt fluxed with an asphaltic base petroleum. Sufficient fluxed asphalt is mixed with the powdered rock asphalt so that the mixture will contain 20% of bitumen. A layer of this mixture, of about 1 in in thickness, is placed on a cement-concrete foundation, which consists of about 4 in of concrete and a layer of cement mortar from ½ to 1 in in thickness. A scattering of gravel is spread on the surface and lightly rolled into the asphalt mastic while the latter is still warm.

Cost. The average cost of this pavement in France is approximately $1 per sq yd. The cost of a similar pavement in England is about $1.40 per sq yd.

Characteristics. Footways constructed with an asphalt mastic have many points of excellence. They are practically non-absorbent, very smooth, without joints, pleasant to walk upon, and easily maintained and repaired. A thickness of mastic of ¾ in will last from 5 to 10 years and sometimes longer on streets where the traffic is not heavy.

Sheet-Asphalt in the form of a thin wearing surface of ordinary asphaltic top mixture on a light concrete base makes an excellent park walk less stiff and formal in appearance than concrete. The base should be about 3 in thick and the wearing surface about ¾ in in thickness.

Lincoln Park Sheet-Asphalt Walks (11). "In Lincoln Park proper there are about 50 000 sq yd of walks built principally of cinders, limestone macadam, and gravel macadam. In 1913, the attention of the commissioners was drawn to the difficulty of keeping these walks in condition for foot travel. In wet weather pools of water would stand in the walks, in dry weather the protruding large stones caused a great deal of discomfiture to the pedestrians, thereby causing many of them to walk on the grass, while in winter the removal of snow was unnecessarily difficult. In deciding upon what methods to use to eliminate the above difficulties the following considerations were borne in mind: (1) Low first cost and low maintenance; (2) the walks should be in harmony with the park surroundings; (3) the utilization of the foundations of the walks as they stood; (4) the walks should be of such a nature as to induce people to use them rather than the grass. With these considerations in view the choice was narrowed down to building Portland cement-concrete walks or resur-

facing with an asphaltic mixture. It was finally decided to build some experimental sections with an asphaltic top. These experiments proved so successful in 1913 that in 1914 enough money was appropriated to cover nearly 40 000 sq yd of walks with an asphaltic wearing surface. About one-third the area, or 13 329 sq yd of walk, were sufficiently compact and rough to pave with a wearing surface only. The balance, or 26 657 sq yd, required a binder and top. The binder used was composed of ½- to ¾-in stone and asphalt. A number of tests showed that the percentage of asphalt used, by weight, was as follows: Minimum 3.85, maximum 5.15, average 4.25%. The binder was laid so that it was ¾-in thick after being rolled with a 5-ton roller. The wearing surface mix consisted of asphalt, limestone screenings, stone dust and bank sand in the following proportions:

Asphalt	10.50%
Passing 200-mesh	12.50%
Passing 80-mesh	18.00%
Passing 40-mesh	36.00%
Passing 10-mesh	13.00%
Retained on 10-mesh	10.00%
	100.00%

"The wearing surface was laid ¾-in thick after being rolled with a 5-ton roller. Immediately after rolling Portland cement was brushed over the surface and then rolled with the 5-ton roller. The cement fills the minute voids in the surface and also improves the appearance of the walks. From the cost report it can be seen that asphalt walks can be laid at approximately 60% of the cost of concrete walks where both binder and top are used, and at about 35% of the cost of concrete where a wearing surface only is used.

Bituminous Macadam Walks (32). "Stake out the position of the sidewalk and excavate the same 2 in, putting the material removed on both sides so as to act as shoulders; then put into the trench excavated the following: A layer of No. 2 trap rock, stones that pass thru a 2-in ring, to a depth of 3½ in, and roll same until compact; cover this layer of stone with a thin coating of No. 3 trap rock, stones that

pass thru a 1-in ring, and roll again; when this second course has been laid and rolled to grade, pour in a good quality of asphalt binder, while hot, at the rate of about 1 to 1¼ gal per sq yd, and cover immediately with screenings from which all dust has been removed; these screenings should be in size from ¼ to ½ in, and should be spread to a thickness of at least ¾ in and then rolled down as soon as possible. The following day the surface should be swept clear of all loose material and a second light application of binder should be poured over and screenings as above mentioned should be spread evenly over the entire surface so as to completely cover the binder and rolled immediately. The rolling down of these screenings immediately after the application of the asphalt binder is very important; therefore the roller should be in constant attendance during the construction of this description of sidewalk, and after rolling down the macadam portion of walk, should roll down the earth shoulders on each side to a width of about 2 ft. A walk 4 ft wide will require about 6¼ tons of crushed stone if rolled to 3-in thickness or 8¼ tons if rolled to 4-in thickness, and about 67 gal of asphalt, for every 100 ft in length, and the excavation of 2.45 cu yd, if cut to the depth of 2 in as previously described."

6. Cinder Walks

In outlying districts where the amount of foot traffic and the value of adjacent property is such as will not warrant the construction of one of the more expensive types of walk, a cheap and fairly satisfactory temporary walk can be built of cinders. The walk should be from 6 to 12 in thick, depending upon the drainage of the subsoil, and built in layers thoroly wetted and tamped or rolled, the top layer being of fine cinders laid to form a good drainage crown. If old planking is available, it should be used as edging on each side of the walk. When practicable, cinder walks should be so laid as to serve as the foundation for a later and more substantial form of walk. Good cinder walks can be built at a cost of from $0.30 to $0.50 per sq yd.

Chicago Practice (28). "Cinder walk consists of not less than 12 in of cinders, usually deposited in 2 layers between 2 rows of 2 by 6-in hemlock plank or curbs, nailed to split cedar posts set 4 ft apart from centers and driven not less than 15 in into the ground. The top of the curbing is set at the grade at which the walk is to be built, 3 in below cement sidewalk grade, and backfilled with earth. The first layer of about 9 in can be either coarse cinders or slag. The second layer of 3 in should be of finer cinders. After these have been compacted a crown of fine, clean cinders is put on and the entire walk rolled with a roller of not less than 500 lb in weight. Some contractors prefer tamping with a regulation concrete tamper to rolling. These walks are objected to in districts which are built up to any extent on account of the cinders being tracked into the houses, destroying floors, carpets, rugs, etc, and are not recommended for any except vacant or sparsely settled districts.

"The average COST of cinder walks in Chicago from 1901 to 1908, based on the total cost, $2 375 359.10, divided by the total mileage 1312.12, was 34.3 cents per lin ft.

Items	Cents per Sq Yd
9 cu ft or ⅓ cu yd at 50 cents, in place	16.67
Lumber at $17.50 per M. 2 ft	3.50
Stakes at 1 cent per lin ft of material	1.12
Nails	0.10
Waste on materials, 1% of value	0.21
Labor, including excavation	4.50
	26.10
Add for superintendence, office expense and profit 15%	3.91
	30.01"

This includes many walks requiring a fill of 2, 3 and sometimes 4 or 5 ft, and can hardly be taken as a fair average cost for the ordinary cinder walk requiring only 15 in of cinders, including crowning. The following itemized cost per lineal foot based on Chicago conditions and Chicago prices would be more nearly correct. Average depth of cinders 1.2 by 6 ft, or 7.2 cu ft in place. Allow for 20% shrinkage, 7.2 + .8 = 9 cu ft loose."

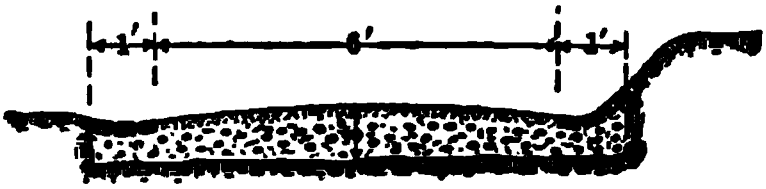

Fig. 5. Gravel Walk with Brick Gutters

7. Miscellaneous Walks

Gravel makes a cheap and satisfactory walk for light traffic, and harmonizes with park treatment better than any other type of walk. The construction should be similar to that of a cinder walk (see Art. 6). The top course of fine gravel should contain sufficient sandy clay or loam to form a compact surface (see Sect. 10). The construction of broken stone walks is similar to that of broken stone roads (see Sect. 11.)

CURBS

8. General Data Relative to Curbs

Curbing of natural or artificial stone is necessary on paved streets and on macadam streets with shallow gutters, to form the back of the gutter, support the sidewalk and protect it from damage by vehicles. The curb must be high enough to prevent water in the gutter from overflowing the sidewalk, without creating an uncomfortable step at street crossings. The height should vary from 5 to 8 in above the gutter, depending somewhat upon the transverse slope of the gutter and the width of the pavement.

Materials and Dimensions. Curbs are usually built of granite, sandstone or cement-concrete. The stones must have sufficient strength and weight to resist the overturning thrust of the sidewalk and sufficient toughness and hardness to withstand the shock and wear of steel tires. They should be from 4 to 8 in wide on top, from 8 to 20 in deep and from 6 to 12 ft in length. The deeper curb is generally used in connection with macadam roadway; the shallow curb with pavements having a concrete base which also forms the base of the curb. Shallow curb is better even for macadam roadways, as it is cheaper, easier to lay and reset and equally as strong as deep curb, if properly laid on the concrete base.

Radius of Corner Curb. Report, Com. Am. Soc. Mun. Imp. (9). Where sidewalks are of sufficient width to permit it, it is recommended that a radius of 12 ft be adopted as a standard corner radius at all corners within 5° of a right angle. At other angles the longest suitable radius should be used by the engineer.

Safety Curbs at Bad Turns (27d). "The principal boulevard entering Huntington Beach, Cal., passes under a railroad, with a bad turn at one end of the underpass. To prevent collisions between vehicles at this point by keeping them on the right side of the road, a double-faced curb has been constructed, 6 in wide on top and 12 in high in the center of the roadway and extending for about 150 ft each side of the subway or underpass. At each end of this curb is a large electric sign warning to 'Keep to the Right.'"

9. Stone Curbs

Granite Curbing should be free from stratification and excess of mica, flint or feldspar. The top and the showing face should be hammer dressed to plane surfaces and as much of the back and of the face below the hammer dressing as is necessary should be pointed to permit of close contact with the sidewalk and gutter respectively. To conform to the slope of the

sidewalk the top should have a bevel toward the face of about ¼ in per ft, with a well defined edge between the face and top. Granite curbs for street and alley returns should be cut in arcs of suitable radii with radial joints.

Cost Data. Granite curbs cost approximately $0.75 per lin ft for 8 by 8-in straight and $1.00 for 8 by 8-in circular; $0.90 for 6 by 20-in straight, and $1.10 for 6 by 20-in circular. See also Table III.

Bluestone Curbs should be from 4 to 6 in in thickness, about 20 in deep and from 6 to 8 ft long, the faces and ends dressed as described for granite curbing. On account of the tendency of this stone to split it can not be cut into arcs, and corners are usually made from other more tractable stone. Curb stones composed of building sandstones are usually sawn on both sides and machine dressed on top with either sharp or rounded edge.

The cost of 6 by 20 in bluestone curb is about $0.50 per lin ft.

Table III.—Character and Cost of Curbs in 1915 in Several Cities

From *Municipal Journal*, Feb. 3, 1916

City	Material	Dimensions in In	Lin Ft	Price per Lin Ft
Oakland, Cal.	Redwood	8 by 12	96 626	$0.11
Oakland, Cal.	Stone	....	2 128	1.48
Denver, Colo.	Cement-concrete	5½ by 30	41 662	0.56
Springfield, Ill.	Cement-concrete	6 by 19	6 942	0.55
Fort Wayne, Ind.	Stone	5 by 18	36 093	0.58
Louisville, Ky.	Limestone	6 by 22	2 818	0.96
New Bedford, Mass.	Granite	6 by 16	21 646	0.91
Saginaw, Mich.	Limestone	4 by 18	21 095	0.55
Butte, Mont.	Cement-concrete	7 by 20	108 600	0.40
East Orange, N. J.	Bluestone	4 by 16	1 665	0.44
Albany, N. Y.	Cement-concrete	7½ by 18	14 424	0.59
Albany, N. Y.	Granite	6 by 12	32 538	0.90
Brooklyn, N. Y.	Cement-concrete	6 by 18	104 100	0.50
Schenectady, N. Y.	Cement-concrete	6 by 18	34 719	0.54
Akron, Ohio	Stone	6 by 18	36 132	0.48
Portland, Ore.	Cement-concrete	6 by 7 by 16	180 084	0.35
Pittsburgh, Pa.	Cement-concrete	6½ by 21	103 467	0.78
Providence, R. I.	Cement-concrete	7 by 18	32 890	0.79
Salt Lake, Utah	Cement-concrete	6 by 16	63 750	0.90
Charleston, W. Va.	Cement-concrete	12 by 24	74 851	0.51

Setting. Shallow curb should be set on a base of lean concrete about 6 in thick laid in a trench dug parallel to the curb line and about 18 in wide. While this base is fresh the stone should be set and adjusted to line and grade by use of heavy wooden mauls. The back of the trench should then be filled with concrete up to the bottom of the sidewalk, the concrete well rammed and covered with earth. In case block gutters are to be laid in front of the curb any portion of the base that would interfere with laying of the block should be removed immediately after the curb is set (see Fig. 1, Art. 2).

Deep Curbs should be set in a trench on a base of broken stone or gravel or other porous material from 4 to 6 in deep. To permit ramming the trench should be about three times the width of the curb. The bottom of the trench should be well consolidated and the base thoroly compacted

by ramming. After the curb is adjusted to line and grade the trench should be filled with the base material placed and tamped in layers to within about 10 in of the top of the stone (see Fig. 2, Art. 3). Where the base material is expensive the backfill is sometimes made with earth. The curb will be much less apt to get out of alignment if the stones are supported at the joints on a bed of concrete extending about 6 in and 12 in up the face and back respectively so as to partially encase the stones at each joint in a small mass of concrete.

STONE BLOCKING or spalls are sometimes used to support the curb, the gravel base being tamped under the curb after it has been set to line and grade on the blocking. While the curb is easier to adjust by this method it is more apt to settle than if laid on a well compacted bed.

The COST of setting 8 by 8-in curb on a 6-in gravel concrete base, including cost of base, is about $0.35 per lin ft; setting 6 by 20 in on gravel base costs about $0.25 per lin ft.

Pittsburgh Specifications for Sandstone Curbs are, in part, as follows:

"**The Curb** shall be of the best quality of Beaver, Baden, or Freeport sandstone, or a sandstone equal in quality thereto, and shall be free from powder cracks, dry and incipient cracks, coal seams, discolorations, and any and all other flaws and imperfections; the color of the stone shall be uniform and subject to the approval of the Director. The finished curb shall not be less than 4 ft long, 2 ft deep and 6 in thick, unless otherwise specified. The top shall be axed to a plane surface, free from all depressions or other irregularities, 6 in in width thruout its full length and the edges cut to true lines. The front of the curb shall be quarry-faced, with 1-in chisel drafts cut along the upper edge and along the joints at right angles to the top. Vertical scores or grooves, spaced 2 to 2½ in between centers, shall be cut in the quarry face with a point, and shall extend 12 in from the top of the curb. They shall be cut straight and true and the bottom of them shall be in the plane of the chiseled drafts. The quarry face shall not in any place project more than ¾ in beyond the plane of the chiseled drafts, nor shall it in any case recede back of said plane. The back shall have a 1-in chisel draft cut along the upper edge and shall be pointed off vertically for 3 in below the top. Joints shall be close and at right angles with the top and face for the full depth and thickness of the stone.

"**Construction.** A trench 18 in in width and 3 ft in depth below curb grade shall be excavated on the curb line and filled with broken stone so as to form a curb drain of the required dimensions. The stone used in the foundation shall be good, clean stone of approved quality, broken to about 3 in sizes. The curb shall be placed on the foundation prepared in accordance with the above directions, each stone being set with a firm bearing thruout its entire length and brought to the established grade and line. The trench at the back of the curb 6 in in width, where there is a sidewalk pavement adjoining, shall be filled with broken stone up to the subgrade of the sidewalk foundation; where there is no sidewalk pavement, the trench at the back of the curb shall be filled within 1 ft of the curb grade. The ditch in front of the curb shall be filled to the subgrade of the roadway pavement with broken stone. The curb shall be backed up to the top with suitable material well rammed, and the placing of broken stone and back-filling shall be done as soon as the curb is set.

"**Where Sidewalks are Disturbed or Damaged** in setting the curb, the Contractor shall repair the same as hereinbelow provided. The loam between the curb and the sidewalk shall be replaced with suitable top soil to a depth of 3 in and the area shall be seeded with a good quality of grass seed. Brick sidewalk pavement shall be relaid for a distance of not to exceed 18 in back from the inner edge of the curb. Flagstone sidewalk pavements extending to the curb shall be removed and recut to fit the curb and then relaid in a workmanlike manner. Concrete sidewalk pavements when damaged or disturbed shall be cut to a true line parallel with the curb and at least 8 in back from the inner edge therefrom and shall be replaced with new work."

Indianapolis, Ind., Specifications for Granite Curbs are as follows:

"All granite curb stone shall be of medium grained granite of even distribution of constituent minerals, uniform in quality and texture, without seams, scales or dis-

colorations, and shall be free from excess of mica or feldspar, and equal in every respect as to the quality of material and dressing to the sample stone in the office of the City Engineer. The minimum length of the curb stone shall be 6 ft except for closures and for corner radial curb where the lengths will be such as are called for on the plans. The depth of the granite curbing shall be 18 in with an allowable variation of not more than 1 in either way. The curb stone shall be uniformly 5 in thick. The top will be dressed with a rise of ¼ in from face to back. The front edge will be dressed to a curve of ½-in radius; the top edge to be pitched to a line parallel to the front edge and shall be dressed to a depth of at least 4 in. The top and the face of the curb for a depth of 12 in shall be smooth pean-hammer dressed without holes or other imperfections. The ends shall be squared so as to afford close joints not to exceed ¼ in for a distance of 12 in down the top."

10. Cement-Concrete Curbs

Proportions and Dimensions. Cement-concrete curbs are usually built in place as two-course work, comprising a core or backing of concrete and a mortar face and top. The proportions of the materials used in the concrete and mortar are the same as for cement walks. Reinforced or armored curb is a form of cement curb in which the edge between the top and face is formed by a metal strip which is set in place while the concrete is being laid and is held in position by lugs imbedded in the concrete. Cement curbs are usually about 6 in wide on top, from 20 to 24 in deep, and divided by suitably constructed joints into uniform lengths of from 6 to 10 ft.

Construction. The curb should be laid in a trench on a base of well compacted gravel, cinders or sand of the same character as the base for stone curbs. If wooden forms are used, they should be of 2-in plank rigidly fastened to stakes so that no displacement can take place during the work of construction. Where much work is being done metal forms will be found advantageous. There are a number of commercial forms on the market which can be had in any desired cross-section. They can be quickly set up and removed, require less skilled labor than wooden forms, and can be used many times over. The back form should first be set up, then the front form to the point where the mortar facing begins. The front form should be given a slight batter to prevent wagon tires from striking the edge. Curb lengths should be formed by inserting metal templates about $^3/_{16}$ in thick at uniform intervals of from 6 to 10 ft. These templates should be withdrawn after the concrete has attained its initial set, leaving the necessary expansion joints. The lower part of the form should be filled with fairly dry cement and tamped up to the point where the mortar facing is to begin. The upper face form is then set up, and plastered with a coating of stiff mortar 1 in thick and the concrete immediately deposited behind it. After this concrete has been rammed the mortar should be carried over the top and floated, and the edge rounded. The upper face form should be removed as soon as possible and the face and top again floated, trowelled and finished with trowel or brush finish, preferably the latter. After the concrete has set sufficiently the lower forms should be removed and templates withdrawn. The latter should be given a thin coating of oil or axle grease to facilitate removal without causing the mortar to flake off. Satisfactory curb has been built in one course, using a slightly richer concrete. While the work is simplified by the omission of the mortar facing, the difficulty of spacing the narrow forms so as to get a uniform surface has prevented the general adoption of this method.

Expansion Joints. The joints between curb lengths will usually take care of expansion. Where the curb is exposed to wide range of temperature,

however, it is well to form additional joints by the use of 1-in planking at intervals of 100 to 150 ft.

Pittsburgh Specifications for Protected Cement-Concrete Curb are, in part, as follows:

"The protected concrete curb may be built at the option of the contractor, either in place, or cast or molded at a point removed from the work.

"**Materials for Concrete Masonry** (see Art. 2, SPECIFICATIONS).

"**The Curb When Built in Place,** shall be constructed in sections between 20 and 30 ft in length. The curbs when so constructed shall be marked off to conform to the scoring of the sidewalk slabs, and sand joints shall be provided between sections as hereinbelow required. When made in the shop, the length of sections shall be 6 ft, except when closures are required. Closures shall be made in strict conformance with the orders of the Director given in the field and the insertion of sections of curb less than 3 ft in length shall not be permitted. The joints between sections of curb built in place shall not exceed ½ in in thickness and shall be made by inserting cross-forms composed of several thicknesses of sheet metal, which shall be carefully withdrawn when the concrete has sufficiently set. The cross-forms shall be drawn before the concrete has sufficiently set to prevent the proper tooling of the edges. The joints shall be carefully filled with dry sand poured into the joint with proper appliances. The exposed surface shall be built to the required grades and shapes by screeding, floating and troweling. The wearing surface shall be formed without the addition of mortar plaster and shall be made by flushing sufficient mortar to the surface by tamping and then finishing as above required. The exposed surface of the work adjoining the forms shall be carefully spaded. No plastering will be permitted. Expansion joints ½ in in thickness shall be provided at each curb return. This expansion joint shall be made by inserting sufficient tar paper to give the required thickness of joint. When completed, the work shall be kept moist for 4 days and protected from traffic and the elements for at least 10 days.

Fig. 6. Cement-Concrete Curb and Granite Block Gutter on Gravel Base

"**The Protected Concrete Curb Not Built in Place,** but cast or moulded in the shop, shall conform to the requirements above specified. The sections shall be cast in rigid forms and shall be allowed to harden for at least 20 days before being transported for placing in the work. They shall be handled, transported and placed with great care and any section that has become spalled or damaged in any manner shall be rejected. Plastering of damaged sections shall not be allowed. The curb blocks shall be set with a firm bearing upon the broken stone foundation herein provided for, and shall be brought to the required line and grade. The joints shall be close and at right angles with the top and face for the full depth and thickness of the curb.

"**The Structural Steel Section** used in the protected curb shall be medium open hearth steel conforming to requirements. Where curb is built in place, the sections of steel protection shall not be less than 10 ft in length and shall be perfectly true to line. When placing concrete, the steel section and anchorage bars shall be rigidly held. A neat joint shall be made between the steel section and the exposed surface of the concrete and the formation of a feather edge will not be allowed. The steel angle used for the curb protection shall be 3 by 2 by ¼ in. Anchorage bars shall be securely riveted with countersunk rivets to the structural sections."

11. Combination Cement-Concrete Curb and Gutter

The combination concrete curb and gutter, on account of its cheapness and neat appearance, is much used on residential streets. The method of construction is similar to that for curb. The concrete base and mortar topping of the gutter are laid, after which the face form of the curb is set and the curb built. The angle between the curb and the gutter should be

rounded to about a 1-in radius. The desired color should be obtained by use of a mixture of sand and lamp black as in sidewalk work. When the curb is built at the same time as the sidewalk, an expansion joint should be left between them. It is advisable to protect the edge of the curb at street corners by some type of armored construction.

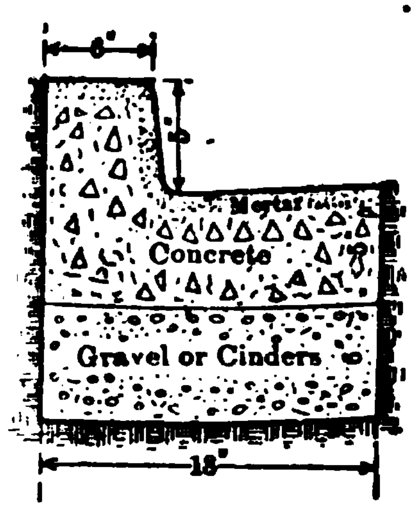

Fig. 7. Combined Cement-Concrete Curb and Gutter

Cost Data. The cost of 1 : 2 : 5 gravel concrete curb and gutter 6 by 8 by 20 in, on a 6-in cinder base, exclusive of cost of forms is between 30 and 40 cents per lin ft. The cost of the labor alone is about $0.11. The combined curb and gutter of Fig. 7 costs from $0.40 to $0.60 per ft, the labor cost averaging about $0.13 per ft.

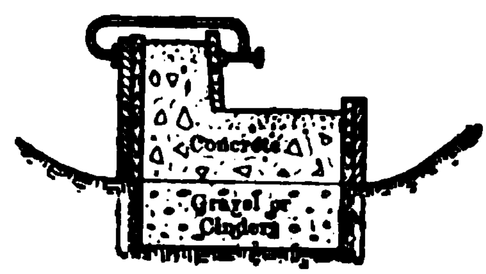

Fig. 8. Wooden Forms for Cement-Concrete Curb and Gutter

Detail Costs to the contractor in Webb City, Mo. (29), of constructing a combined cement-concrete 9 by 6 in curb and 24 in gutter: Concrete for curb and gutter was composed of 1 part of Portland cement to 2 parts of sand to 4 parts of crushed stone. The finish on curb and gutter was 1 in in thickness and was composed of 1 part of Portland cement to 1 part of river sand.

Labor and Materials for 2900 Lin Ft

	Cost per Lin Ft
Labor:	
1 foreman, 99 hr at $0.666	$0.0227
2 finishers, 95 hr at $0.30, 14 hr at $0.50	0.0128
2 form setters, 198 hr at $0.2333	0.0159
2 mixing and placing mortar, 198 hr at $0.233	0.0159
5 mixer men, 464 hr at $0.222	0.0356
Total for labor	$0.1024
Material:	
Cement, mortar and concrete, 1291 sacks at $0.40	$0.1767
Sand, mortar, 457 ½ cu ft at $0.07	0.0116
Gravel, concrete, 122 cu yd at $0.50	0.0210
Gravel, sub-base, 161.1 cu yd at $0.50	0.0278
Total for material	$0.2371
Total for labor and material	$0.3395

GUTTERS

12. General Data Relative to Gutters

Paved Gutters should be provided for roads on steep grades or on fills where there is danger of washouts, as well as for city and suburban streets. On streets provided with a curb, the gutter should have a shallow cross-section similar to that of the roadway, the curb being utilized to form the back of the gutter.

Where No Curb Exists the gutter is usually built of circular section or in the form of a flat V, with the steep side next to the walk. On most paved streets the portion of the pavement adjacent to the curb forms the gutter. With asphalt and macadam pavements, the gutter is usually built of vitrified brick, stone-block or cement-concrete; in the case of sheet-asphalt, to prevent its deterioration from standing water; and in the

case of macadam, to prevent wash. Brick gutters are desirable on a sheet-asphalt street, whether absolutely essential to prevent deterioration or not, as they add materially to the finished appearance of the pavement.

Where a Curb is Used, the gutter should not be so deep as to make an inconvenient step for pedestrians, nor so shallow as to be liable to overflow. Depths of from 5 to 8 in will generally be found sufficient. The longitudinal grade is usually parallel to the curb, tho on very flat grades, the gutter is sometimes given an increased slope toward the catch basin.

Flat Gutters are usually built of cement-concrete, vitrified brick or stone-block, tho flag-stones are sometimes used for this purpose. Concrete gutters are practically always constructed in combination with curbing as described in Art. 11.

Table IV.—Character and Cost of Gutters in 1915 in Several Cities

13. Brick Gutters

Construction. Brick gutters should be constructed of good quality vitrified paving bricks on a concrete base. The bricks should be laid on a paving bed about ½ in thick, composed of a 1 : 4 mixture of dry cement and sand, with lengths at right angles to the direction of the street and breaking joints longitudinally. The joint between the gutter and roadway pavement should be continuous. The type of construction in which the outer edge of the gutter is left with alternately projecting bricks to tooth into the pavement has not proved satisfactory owing to the difficulty of consolidating the paving material between the projecting bricks. Narrow gutters are to be preferred to wide gutters since the joint in the former case is less exposed to the action of passing traffic. The bricks should be rammed in the same manner as a brick sidewalk and then thoroly grouted with a thin grout of neat cement. Brick gutters are usually made from 14 to 27 in wide. An 18-in vitrified brick gutter on a 6-in concrete base, costs about $2.25 per sq yd (see Fig. 1, Art. 2). See also Table IV, Art. 12.

Spokane, Wash., Specifications are, in part, as follows:

"**Bricks.** Where shown on the plans, brick gutters shall be constructed next to and adjoining the curb. The brick used in the gutters shall be what are termed Class..... in the following specifications. All brick shall have the following dimensions: 2⅝ by 4⅛ by 8⅜ in and shall not vary from these dimensions more than 5%. In place of brick of the above dimensions there may be used vitrified blocks 3¼ by 4⅛ by 8⅜ in. When broken, the brick or blocks shall show a dense, stone-like body, uniform in color inside, free from lime, air pockets, cracks or marked laminations. Kiln marks must not exceed 3/16 in and one edge at least to show but slight kiln marks. All bricks or blocks so distorted by burning, as to lay unevenly in the pavement, shall be rejected.

"**Tests.** The absorption of moisture of any brick or portion thereof shall not exceed 3% of the weight of any sample after thoro drying and immersion in water for 3 consecutive days. All bricks or blocks shall be subject to inspection before and after laying and rolling. Brick or blocks to be accepted as Class 1 must not lose more than 20% of their weight after being subjected to the rattler test as hereinafter set out. All brick or blocks to be accepted as Class 2 must not lose more than 35% of their weight after being subjected to the same test.

"**Method of Laying.** On the concrete foundation heretofore laid shall be spread a layer of cement mortar mixed dry and composed of 1 part cement and 3 parts sand not less than 1 in thick, in which the gutter brick or blocks shall be thoroly and firmly bedded. The brick or blocks shall be laid on edge, close together, in straight lines, and with their length parallel to the curbs. The joints shall be broken by a lap of not less than 3 in. The surface of the brick gutters must be true to crown and grade. After the brick or blocks have been laid, the surface shall be swept clean, rolled with a baby steam roller, sprinkled with water, and thereupon the joints and spaces between the bricks or blocks completely filled with cement grout. The grout must be kept continuously stirred while pouring. A second pouring shall be required if in the opinion of the Engineer the first pouring has not completely filled the joints. The cement grouting used shall consist of 1 part cement and 2 parts sand. For a period of 10 days the gutter shall be sprinkled with water if so directed by the City Engineer."

14. Stone Gutters

Granite Block gutters are usually laid on a gravel base about 6 in thick, well compacted and over-laid with sufficient fine bank gravel or sand to form a paving bed for the blocks. After the blocks have been rammed, the joints are filled with firm bank gravel (see Fig. 6, Art. 10). Deep gutters are usually of the type shown in Fig. 9, and are generally constructed with granite block or cobblestone, laid on gravel base. For cost data, see Table IV, Art. 12.

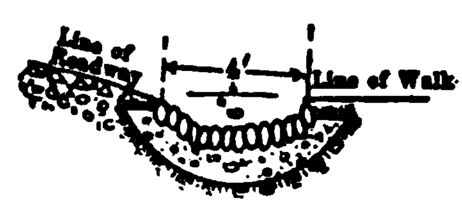

Fig. 9. Barrel Gutter of Cobblestones on Sand Bed and Gravel Base

Los Angeles, Cal., Specifications are as follows:

"**Sand Cushion.** Upon the concrete base laid as above specified and swept free from all dirt and rubbish, shall be spread a layer of sand 2 in in depth. The sand need not necessarily be sharp, but it must be screened, dry and free from more than 3% of loamy matter.

"**Granite Blocks** shall be of sound, durable stone, free from weather marks or seams, and uniform in quality. They shall have dimensions as follows: Length from 8 to 12 in; width from 3½ to 4 in; depth from 6 to 6½ in. They shall be of rectangular form on top and sides, and free from bunches or irregularities which will prevent them from lying closely together. Any blocks having projections or knobs larger than ½ in will be rejected.

"**Laying the Blocks.** Upon the sand cushion shall be set the granite blocks with their longest dimension parallel to the line of the curbs. Each course shall be laid straight and regular with sides perpendicular to the surface and joints broken to the extent of at least 3 in. In no case shall stones of different widths be laid in the same course. All joints shall be close joints, none to exceed ¾ in in width. The blocks must then be thoroly rammed with a rammer weighing not less than 60 lb. Each block must be struck not less than 3 blows and the ramming shall be continued until the

blocks are brought to an unyielding bearing, with a uniform surface, true to line and grade. Any block which, after ramming does not conform to the required surface shall be removed, reset and retamped. No ramming shall be done within 20 ft of the work that is being laid. The joints shall then be filled with a grout made of 1 part of Portland cement and 2 parts of clean, sharp, screened sand. The sand and cement shall be mixed dry until the mixture is of uniform color. Water shall then be added until the mass is of the consistency of thin cream. It shall then be applied to the surface by means of scoop shovels and shall be thoroly swept into the joints until all interstices are filled and the gutter has a smooth and uniform surface. The blocks shall be well sprinkled before grouting. The entire surface of the gutter shall be kept damp for 10 days and no traffic shall be allowed before the expiration of this time."

Cobble Gutters are the cheapest form of gutters, but require frequent cleaning and weeding. Cobbles suitable for gutters should be from 4 to 6 in long and from 2 to 4 in wide. The cost of cobble gutter shown in Fig. 9 is about $0.40 per sq yd exclusive of the cost of cobblestones. When suitable cobbles can be obtained in connection with the work of grading the road, their cost will average about $0.30 per sq yd, making a total of about $0.70 per sq yd for labor and materials.

R. I. State Board of Public Roads Specifications are, in part, as follows:

"The earth, stone and other materials necessary to be removed shall be taken out for a depth of 10 in below the top of the finished surface. All objectionable or unsuitable material found below that depth, shall be removed and shall be replaced with clean sand or gravel which shall be well compacted by ramming. Upon the subgrade thus formed shall be placed, as a bed for the paving stones, a layer of clean sharp sand of such depth as may be required to bring the work to grade. The stone shall be hard, durable cobble or kidney stones, not less than 4 in nor more than 8 in long and not less than 4 in nor more than 6 in wide. The work shall proceed from the sides of the gutter toward the center, keeping the sides in advance of the center. No stone shall be laid on its longest side. After the stones have been set, all joints and cavities shall be filled with clean, fine sand and then the stones shall be carefully and thoroly rammed until no further settlement occurs. If in ramming, any of the stones do not come to the correct grade, they shall be taken out, reset and again rammed. During the ramming the joints shall be kept full of clean, fine sand."

HIGHWAY SIGNS

15. Distance and Direction Signs

Road Signs giving information which will aid in the safe and convenient operation of vehicles are an important feature of a modern highway. The necessity for properly marking roads designed to carry high speed, thru motor traffic is generally recognized, and the practice of including the erection of such signs in the work of construction of the road itself is becoming more common.

Conditions in United States (17). "The American road system is as yet so imperfectly developed nationally and is so rapidly and constantly changing that no national system of road marking can be adopted until the road system itself has been very much more finally and permanently established. In the United States particularly there are numerous and widely separated important centers from which main routes radiate, which condition precludes at this time any attempt to establish a national numerical or color scheme of distinguishing highways. The scope for consideration therefore narrows down to the determination of a definite marking system for main traveled highways considered singly."

Classification. Road signs are of two general classes, distance and direction signs, and warning signs. Each class of signs should as far as practicable be uniform in size, form, color, height, distance from edge of road and location.

Information as to Distances and Directions is usually combined in a single sign located at cross-roads and forks. Intermediate distance signs,

in the form of mile posts, while not essential are desirable on trunk roads.

Materials. Mile posts should be of stone or concrete. Signs should be of malleable cast iron, cast iron or wood. The cost of iron signs precludes their general use at present. Wooden signs should be made of 1-in material, substantially built and strongly bolted to iron or wooden posts firmly set in the ground. The signs should be set as nearly or practically at a uniform height, about 6 ft, above the surface of the road.

Block Lettering should be used of a color contrasting with the body of the sign. A black inscription on a white ground will make the most legible sign.

Examples of Signs. A form of iron sign successfully used by the Automobile Club of Minneapolis is made of malleable cast iron, 30 in long, 5/8 in thick, each line is 3 in wide with 2-in letters, border and letters raised about 1/8 in. The casting is galvanized, the ground then painted two coats of white, letters, figures and border painted black; and the whole finished with a coat of spar varnish. The sign is bolted to a 2½-in galvanized iron pipe set in a concrete base. The cost of these signs erected is given as about $7. This sign was adopted after it had been found impossible to maintain wooden signs owing to their destruction by hunters. Fig. 10 shows a type of wooden sign recommended by Messrs. Evans and Batchelder. This sign is 36 by 13 by 1 in thick, the size of the letters of the three rows being 4, 3 and 2 in respectively.

Evans and Batchelder Report to 3rd Int. Road Cong., 1913 (17).

"STONE SIGNS. American state roads should have well designed mile stones at least, and preferably ½ and ¼ mile stones. Sizes and forms should be absolutely uniform, for each type, and in all states. The face of mile stones should bear the names of the principal terminal points of that road section, in each direction, and numbers giving the distance in round miles under each name to these points. On the side of the stone towards the approaching traveler should appear the name of the next settlement in that direction, with a number giving the round miles distant; and on the other side of the stone visible after passing should appear the name of the last settlement in the reverse direction with a number giving the round miles distant. The ½ and ¼ mile stones, if used, need only be marked with ½ or ¼ or not at all. The precise size and form of stone posts together with the lettering thereon should be absolutely determined by careful engineering design, and the same type of post with its appropriate lettering should be absolutely maintained thruout the country. The lettering should be reduced to a minimum, should be plain, large as possible and of such formation as to be as durable as possible; and a uniform principle of location along the roadside should be rigidly adhered to.

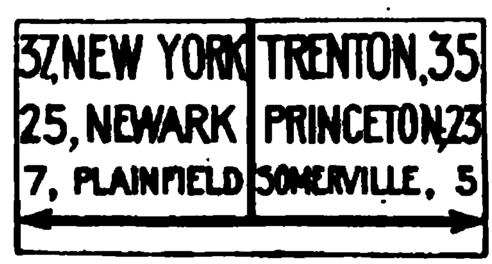

Fig. 10. Wooden Road Sign

"ELEVATED SIGNS. These naturally divide themselves into, (1) distance and direction signs; (2) police and warning signs; (3) warning symbols. Each class of these elevated signs should be as far as possible absolutely uniform in size, form, color, and regular height, distance from edge of road, and location with respect to the physical road peculiarity which it purports to interpret. These factors are all very largely controllable, and merely require rigid adherence to a definite, fore-ordained system of design, construction and location by all authorities touching them. In general, signs should be strictly limited in number of classes. Too few classes do not give adequate information and too many are confusing. The organic law should adequately protect all permissible signs, and should rigidly exclude those of an advertising nature from the highway. The higher the speed of a passing vehicle, especially under conditions of poor light, the more necessity there is for a uniform and simple sign system. Therefore, there should be as few classes as possible; with a uniform size assigned for each class; with a regulated system of plain block lettering showing the relative importance of points visibly by the difference in the size of letters all with a uniform, simple, obvious, visible, and highly contrasting color scheme, and uniform as to location in

relation to the highway points described; and uniform as to height above the road and the distance from the road, as far as possible for the respective classes of signs. As to material, cast iron signs on suitable iron posts are admittedly the best, but few countries can afford the expense involved. For American use, therefore, clear white pine, a very durable wood in form and substance, seems the best, 1 in thick, strongly cleated together, heavily riveted, the body well painted white, the information well painted in black. These signs should be bolted strongly to suitable wooden posts well set in the ground. All signs on posts should be 6 ft on the average above the road surface. Signs on houses or other supports should not be over 9 ft above the road surface. Signs at a uniform height above the road for each class are much more easily read at speed, as any observer on a railroad train will notice when passing a series of well designed stations. If a sign of a certain class is 15 ft high on a wall or building at one point and 4 ft high on a fence at another, with varying distances for others, the eye of the traveler wastes time in locating the sign instead of having all the time available for reading the sign, which should be definitely anticipated at a uniform height above and distance from and location alongside the highway. The same considerations demand as nearly as possible a uniform distance from the highway and a uniform relation to road vagaries. For instance, at cross-roads, a descriptive sign should always be at a uniform location; and a warning sign of a steam railroad crossing or other obstacle or danger should always be a uniform distance back of the obstacle warned.

"DETAILS OF DISTANCE AND DIRECTION SIGNS. Double distance and direction signs should be 36 in long by 17 in deep if carrying three rows of names and mileages, with a fourth row giving authority or the club name responsible for the sign; and 36 in long by 15 in deep if without the fourth line. All letters and numbers must be of the plainest and most obvious block type, the largest or most important row of letters being 4 in deep; the second, reading down, 3 in deep; the third 2 in deep, and the club or location authority 1 in deep. These letter and number sizes, while sufficiently clear and obvious, do not make the sign unduly large or costly. Single distance and direction signs should be 20 in long by 17 in deep, if with the fourth row of lettering, or 15 in deep, without the fourth row of lettering. Single direction signs should be 6 in by 21 in for use in addition to all other signs for constant duplication along the highway where a road section happens to be obscure or tangled."

Wallis Report on Color, Sidewalk Signs and Illumination of Signs (34).

"COLOR. Maximum legibility requires strongly contrasting color combinations. Black letters on a white background are common, but more popular at present is a white letter on a ground of royal or ultramarine blue, most of the enameled iron signs being in these colors. The latter combination is more attractive in appearance than black and white and is very legible by day or night. Silver gray or aluminum on black is particularly effective, especially after dark. Gilt or gold-leaf letters on black used on wooden signs in Boston are dignified and effective. Red is seldom used, altho Washington, D. C., uses clear glass letters blown in a ruby glass plate, and in several northern New Jersey towns ruby letters are blown in a clear glass background. Washington also uses a cast aluminum sign painted slate-gray with letters outlined in gold leaf. Aluminum letters on black enameled steel are used in Rochester, N. Y., and zinc on black lacquered plates in Fall River, Mass. San Francisco used white letters on brown-enameled plates. Aluminum bronze letters on a green background are used in Minneapolis.

"SIDEWALK SIGNS. Several cities have placed street names on sidewalks near the curb at the intersection, on the top or face of the curb, and on gutter plates. These can not be read from cars or other vehicles, where there are many pedestrians, or when there is snow on the sidewalks. In some cities brass or cast iron name plates are set in the sidewalk flush with the surface; in others, tile or composition letters of contrasting color are set into the concrete when it is laid, or the letters are stamped into the green concrete with brass dies. Fremont, Neb., uses cast iron gutter plates with the name cast in the surface. A few cities paint the name on the face of the curb.

"ILLUMINATION AT NIGHT. This has been effected by using transparent, translucent, or perforated signs of various types, supported in metal frames or brackets around street lamps. With cluster incandescent electroliers the signs are usually placed around the central globe. An inexpensive and fairly common practice is to paint the street names directly on the face of the globe. In some cases the name is blown into the glass. On the more important corners of Washington, D. C., a lantern is

used with sides of ground glass on which the name is painted in black, inside which a small gas or electric lamp is placed."

16. Warning Signs

Warning Signs or Symbols should be used to give notice of sharp turns, grades, road and railroad crossings or other physical features of the road which call for the exercise of additional care, as well as to give information of special speed or police regulations. While a very great variety of design and types of danger, precautionary and police signs exists, it is recognized that they should conform as far as practicable to the following requirements: They should be conspicuous and easily and quickly read, and therefore concise; should specify the character of danger to be guarded against and should be located at such a distance from the danger point as to give ample time to be acted upon.

At Railroad Grade Crossings dependence should not be placed solely on the railroad danger sign located on the right-of-way, but additional signs should be erected several hundred feet distant from the crossing. An excellent system of grade crossing signs is used in one state having a number of improved roads crossing a trunk line carrying frequent express service; a sign is placed 500 feet from the crossing with the legend " Railroad Crossing 500 Feet." Two hundred and fifty feet beyond is a second sign reading " Railroad Crossing 250 Feet" and, where power is available, this sign is lighted by several incandescent lamps.

The Inscription should be conspicuous and brief. Letters from 6 to 8 in in height should be employed. The following are some of the forms of inscription commonly used: Danger; Danger Sharp Curve; Slow; Slow Down; Sharp Curve.

Forms of Warning Symbols Adopted by the International Road Congress, which embodies all the essential features of a good sign are shown in Figs. 11, 12, 13, 14 and 15. The standard sign is 18 by 24 in, painted black with white

Fig. 11. Cross Roads

Fig. 12. Turn to the Right

Fig. 13. Turn to the Left

Fig. 14. Dangerous Descent

Fig. 15. Railroad Crossing

symbols. If desired, the name of the club erecting the sign can be painted in black on a yellow band across the top of the sign. These signs cost about $0.50, exclusive of the cost of erection.

Traffic Regulation Signs should be erected on the main highways entering a city. Speed zones within the city and individual streets for which special regulations are applicable should also be marked. A speed sign should have the maximum permissible speed in conspicuous letters, with the town or zone limits and the authority for the ordinance in a smaller inscription. On city streets the signs should be located at the curb, about 8 ft above the sidewalk and as small as practicable, consistent with conspicuousness and legibility.

Use of Portable Traffic Signs (18). **"Many municipalities, both large and small, are using fixed or portable signs for several purposes connected with traffic control, the more common being to prevent cutting of corners at street intersections; to regulate the parking of vehicles; and to give warning of dangerous conditions.**

"Traffic signs should be uniform in SHAPE AND SIZE and carry the least amount of

wording which will make the meaning plain. Circular disks from 12 to 18 in in diameter are becoming common, as they are readily distinguished from the advertising signs which are so frequently seen on streets and highways. To be of service, the sign must attract attention and for this reason strongly contrastihg COLORS are used. Red, as the universal danger or warning color, is the one most commonly used, the lettering ordinarily being in white or aluminum letters on a red background, in order that the red may predominate and cause the light color to show plainly on the dark background. Other combinations used are black and white, black and aluminum, and blue and white.

"PORTABLE STANDARDS are usually about 5 ft high and made so that the instructions 'Drive to the Right,' or some similar notice is visible from each of the four directions of approach. They should be so constructed that they will not be damaged when tipped over. If they are to be left in place at night, they should be fitted to hold a lamp or lantern, unless they are well lighted by nearby street lamps.

"Many municipalities find it necessary to restrict the PARKING of vehicles in certain districts to prevent the blocking of streets and interference with business. Some prohibit parking in front of hotels, theaters and other places where a large number of patrons arrive or leave by motor vehicles. Others set aside whole blocks where vehicles are not allowed to stand, and some allow parking in the center of the street or on one side only. On account of this lack of uniformity in different localities, areas in which parking is restricted or prohibited should be plainly marked.

"For WARNING OR CAUTION SIGNS marking danger points, bright red disks 18 in in diameter on permanent posts or standards outside of the traveled portion of the street are very effective. Signs smaller than 18 in should not be used, as they could not then be read or would not sufficiently attract attention at a considerable distance. Warning signs should be 7 or 8 ft high, and placed 50 to 75 ft from the point of danger."

HIGHWAY BRIDGES

CULVERTS**

RETAINING WALLS**

FOUNDATIONS**

GUARD RAILS**

HIGHWAY BRIDGES

1. Location and Waterway for Highway Bridges

Preliminary Investigations. The great majority of highway bridges are built across rivers and streams, altho it oftentimes happens that a highway must be conducted over a railroad right-of-way, and sometimes over another highway which is at a different level. Special local conditions

*By E. H. Rockwell, Professor of Structural Engineering, Tufts College.
**By Charles B. Brown, Professor of Civil Engineering, University of Maine.

may influence the location. If the river is navigable, Government regulations must be met. If the bridge is to connect a highway in a thickly settled community, its location will be practically determined. If it is a country bridge, oftentimes the highway approaches may be changed to allow the most economical location. In deciding upon the site, it is usually necessary to make a contour survey of one or more locations. Such a survey should show enough topography so that a careful study may be made in the office of existing conditions, and should include soundings of the river-bed, together with as much data as possible regarding its composition. It is oftentimes necessary to make borings to determine the character of the subsoil and to locate a suitable foundation for piers and abutments. The elevation of high and low water, as well as an average high stage, should be determined, together with some idea of the frequency of occurrence. In addition, it is well to have information regarding the velocity and set of the current. After the definite site has been decided upon, it is necessary to make an accurate location of the center line of the bridge in order to obtain its true length and definitely locate piers and abutments. This is usually done by triangulation, and consists of measuring the distance between two points, one on each side of the river, by laying off a carefully measured base from one of these points along the shore or bank of the river, and measuring the angles formed at each end of the base by lines to the point on the other side of the river. The degree of precision necessary in measuring the base will depend upon existing conditions, and may range from the use of a standard 300-ft steel tape, making corrections for temperature, grade, etc, to the use of an ordinary 100-ft steel tape. The course should be measured several times and a mean result obtained. For refined methods see Sect. 5, Arts. 6 and 35 (4), (14) and (17). The ordinary case for highway bridges usually will be satisfied by careful work with a 100-ft steel tape used on the base, and for the angles by the use of a properly adjusted transit which reads to single minutes, provided each angle is repeated, first to the right and then to the left, and a mean value taken. With these two angles and the included side, the distance between the two sides of the river may be determined by trigonometry.

The Waterway beneath the bridge depends upon the amount of congestion caused by piers and abutments. The channel must not be unduly obstructed, so that in time of freshet the structure will not be endangered by the ice, swirls and eddies causing washouts, and floating logs and débris. The chief point to be determined is the rise in water level which occurs just up stream from the piers, the rise at the piers being less than this amount. The average case may require no mathematical investigation, the judgment of the engineer being used to obtain a proper elevation of the bridge above high water. In cases where the depth in proportion to the width is considerable, or where the river is spanned by a number of plate girders or arches, the following formula by Merriman (16a) may be used. In extreme cases, the problem may become more complicated, requiring a more careful study by the principles of hydraulics. In any case, such solutions are apt to be more or less approximate, and the judgment of the engineer must be taken into consideration.

$$C\sqrt{2g}\ \left[\tfrac{2}{3} B\ (H+h)^{\frac{3}{2}} + b\, D\, (H+h)^{\frac{1}{2}} \right] = q$$

B = original width, b = contracted width, D = depth of water before congesting the opening, H = rise in water level, q = discharge of stream in cu ft per sec, h = head due to velocity of approach. The coefficient C

may be taken as 0.9 for piers with round ends, and 0.8 for triangular cut-waters. In order to arrive at such determinations, data upon the volume of discharge is necessary.

Discharge Data may come under one of three cases. (1) Records at some gauging station near the location. (2) Records at some point on the same river some distance away, or on a similar river. (3) No records at all. In case 2, find drainage area at site of bridge and consider discharges as being proportional to drainage area. Case 3 will seldom occur where it can not be reduced in some way to case 2. Note that flood measurements of discharge are usually less reliable than medium or low water measurements.

2. Economical Length and Cost of Highway Bridges

Span Length. In determining the number of spans to use, consideration should be given to the principle that the cost of the superstructure should equal the cost of the substructure in order for the total cost to be a minimum. This requires a careful preliminary study, especially where more than one span is necessary, or where it is a question of one long span or two shorter spans. Estimates should be made of the cost of the bridge itself, and of the piers and abutments, for different combinations. The first cost of a bridge is not the only item which should receive consideration in an economical study of the problem. The life of the structure should be considered. Many highway bridges of cheap construction have proved too light and altho stable for a time, they have lacked stiffness when subjected to a moving load and have soon become unfit for use without constant repairs. A properly designed steel highway bridge if kept painted should have a life of at least from 40 to 50 years. Wooden floors must be replaced about every 4 years. Reinforced concrete bridges should last indefinitely.

The Economic Depth and Panel Length of trusses as determined by experience are shown by the following tables as given by Ketchum (15b), in "Structural Engineers' Handbook."

Depths and Panel Lengths of Thru Highway Bridges Used by American Bridge Company

Type of Truss	Span in ft	No. of Panels	Ratio of Depth to Panel Length
Pratt, riveted and pin-connected	80 to 90	5	1.0
	96 to 126	6	1.0
	133 to 147	7	1.0
	152 to 168	8	1.1
Quadrangular, Warren riveted	80 to 90	5	1.0
	90 to 114	6	1.0
	119 to 133	7	1.0
	135 to 152	8	1.1
Camel-back, pin-connected	162 to 180	9	1.0, 1.159, 1.25, 1.29
	190 to 220	10	1.0, 1.238, 1.28, 1.43
Petit, pin-connected	240 to 276	12	1.0, 1.397, 1.555, 1.714
	294 to 322	14	1.0, 1.36, 1.60, 1.84, 2.00

Types of Bridges Adopted in the American Bridge Company's Standards

Pratt, pin-connected trusses	80 to 168 ft span
Pratt, riveted trusses	80 to 168 ft span
Warren, quadrangular, riveted trusses	80 to 152 ft span
Inclined chord Pratt (camel-back) pin-connected trusses	168 to 220 ft span
Petit trusses, pin-connected	220 ft span and over

The Cost of Bridges includes cost of material, fabrication, erection and transportation. The cost of fabrication and erection can not be accurately given but the following figures taken from Ketchum's "Structural Engineers' Handbook" (1914) (15b) may be used as a guide for estimates.

"The cost of material varies with the market and may be found quoted in the various engineering journals.

"The cost of fabrication includes cost of drafting and cost of shop labor. To this should be added cost of mill details for materials ordered directly from the rolling mill which is cut to exact length and punched, such as joists and similar members. The cost of drafting will be from $1 to $2 per ton where sketch details are used, and from $2 to $4 per ton where members are detailed separately. The costs of shop labor may be estimated for the structure as a whole according to the following data, and are exclusive of fence and joists and include detailing and one coat of shop paint. For reaming add 0.15 cents per lb.

Approximate Shop Costs of Pin-Connected Bridges

Bridges weighing 5 000 lb and less	1.30 cents per lb
Bridges weighing 5 000 to 10 000 lb	1.20 cents per lb
Bridges weighing 10 000 to 20 000 lb	1.00 cents per lb
Bridges weighing 20 000 to 40 000 lb	0.90 cents per lb
Bridges weighing 40 000 to 60 000 lb	0.80 cents per lb
Bridges weighing 60 000 to 100 000 lb	0.75 cents per lb
Bridges weighing 100 000 to 150 000 lb	0.70 cents per lb
Bridges weighing 150 000 lb and up	0.65 cents per lb

Approximate Shop Costs of Riveted Truss Bridges

Bridges weighing 5 000 lb. and less	1.15 cents per lb
Bridges weighing 5 000 to 10 000 lb	1.00 cents per lb
Bridges weighing 10 000 to 20 000 lb	0.90 cents per lb
Bridges weighing 20 000 to 40 000 lb	0.85 cents per lb
Bridges weighing 40 000 to 60 000 lb	0.75 cents per lb
Bridges weighing 60 000 to 100 000 lb	0.70 cents per lb
Bridges weighing 100 000 to 150 000 lb	0.65 cents per lb
Bridges weighing 150 000 lb and up	0.60 cents per lb

Approximate Shop Costs of Plate Girder Bridges

Spans weighing 10 000 lb and less	0.90 cents per lb
Spans weighing 10 000 to 20 000 lb	0.85 cents per lb
Spans weighing 20 000 to 40 000 lb	0.75 cents per lb
Spans weighing 40 000 to 60 000 lb	0.70 cents per lb
Spans weighing 60 000 to 100 000 lb	0.60 cents per lb
Spans weighing 100 000 lb and up	0.50 cents per lb

"**Card of Mill Extras.** For cost of fabrication of joists estimate according to the following cost of mill details: If the estimate is to be based on card rates it will be necessary to have the subdivisions a, b, c, d, e, f, r, etc, as follows:

a = 0.15 cents per lb. This covers plain punching one size of hole in web only. Plain punching, one size of hole in one or both flanges.

b = 0.25 cents per lb. This covers plain punching one size of hole either in web and one flange or web and both flanges. The holes in the web and flanges must be of the same size.

c = 0.30 cents per lb. This covers punching of two sizes of holes in web only. Punching of two sizes of holes either in one or both flanges. One size of hole in one flange and another size of hole in the other flange.

d = 0.35 cents per lb. This covers coping, ordinary beveling, riveting or bolting of connection angles and assembling into girders, when the beams forming such girders are held together by separators only.

e = 0.40 cents per lb. This covers punching of one size of hole in the web and another size of hole in the flanges.

f = 0.15 cents per lb. This covers cutting to length with less variation than ± ⅜ in.

r = 0.50 cents per lb. This covers beams with cover plates, shelf angles, and ordinary riveted beam work. If this work consists of bending or any unusual work, the beams should not be included in beam classification.

"Shop Costs of Individual Parts of Bridges. The cost of fabricating joists and other similar members should be estimated on the basis of mill details, which see.

"Eye-Bars. The shop cost of eye-bars varies with the size and length of the bars and the number made alike. The following costs are fair averages: Average shop costs of bars 3 in and less in width and ¾ in and less in thickness are from 1.20 to 1.80 cents per lb, depending upon the length and size. A good order of bars running 2½ in x ¾ to 8 in x ¾ in, and from 16 to 20 ft long, with few variations in size, will cost about 1.20 cents per lb. Large bars in long lengths ordered in large quantities can be fabricated at from 0.55 to 0.75 cents per lb. To get the total cost of eye-bars the cost of bar steel must be added to the shop cost.

"Chords, Posts and Towers. In lots of at least four, the shop cost is about as follows: Members made of two channels and a top cover plate with lacing on the bottom side, or two channels laced on both sides cost about 1.00 to 0.85 cents per lb for pin-connected members weighing from 600 to 1500 lb; and about 0.80 to 0.70 cents per lb for members with riveted end connections. Members made of four angles laced cost from 0.80 to 1.10 cents per lb for members with riveted ends. Members made of two angles battened will cost about 0.50 cents per lb. Angles used without end connections should have their cost estimated on the basis of mill details, which see.

"Pins. The cost of chord pins will vary with the size, number and other requirements. The shop cost of chord pins and nuts may be estimated at from 2 to 3 cents per lb. Rollers will cost practically the same as pins. Rolled rounds (pin rounds) are used for making pins and rollers.

"Latticed Fence. The shop cost of light, simple, latticed fence, made of two 2 in x 2 in angles, with double lacing and about 18 in deep, will be about 2 cents per lb; while the shop cost of latticed fence, with ornamental rosettes or ornamental plates, may be as much as 4 to 5 cents per lb.

"Floor Beams and Stringers. Plate girders used for floor beams and stringers will cost from 0.60 to 1.25 cents per lb, depending upon the weight, details and number made at one time. Floor beams made of rolled I-beams will cost from 0.50 to 0.75 cents per lb.

"The Cost of Erection includes (1) cost of hauling to the site; (2) falsework and placing steel in position; (3) riveting; (4) painting. Hauling may be estimated as about 25 cents per ton mile plus from 25 to 50 cents per ton loading and unloading. Falsework under ordinary conditions will cost \$6 to \$8 per thousand plus the cost of the timber. If piles are to be driven for a foundation, their cost will vary with local conditions. These may be estimated as from 20 to 50 cents per lin ft in place. The cost of placing and bolting is about as follows:

Spans 30 to 60 ft	\$12 to \$15 per ton
Spans 60 to 100 ft	10 to 12 per ton
Spans 100 to 150 ft	9 to 10 per ton
Spans 150 ft and over	8 per ton

"The cost of riveting in pin-connected spans will vary from 7 to 12 cents per rivet while the cost in riveted trusses will be from 6 to 10 cents per rivet. The number of rivets in thru riveted spans will be about 250 to 300 for a four-panel bridge, and 1300 to 1500 for a nine-panel bridge. Pin-connected bridges have about one-third to one-half as many.

"Transportation depends upon freight rates between different points, information regarding which may be obtained from the railroads.

"Cost of Painting. Structural steel should be painted with one coat of linseed oil, linseed oil with lampblack filler, or red lead paint at the shop; and two coats of first-class paint after erection. The two field coats should be of different colors, care being used to see that the first coat is thoroly dry before applying the second coat. Light structural work will average about 250 sq ft and heavy structural work about 150 sq ft of surface per ton of metal, and will take about ½ gal of paint for the first coat and ⅜ gal for the second coat per ton of steel. A good painter should paint 1200 to 1500 sq ft of plate surface or 300 to 500 sq ft of structural steel work in a day of 8 hr. A thick red lead paint mixed with 30 lb of lead to the gallon of oil will take fully twice as long to apply as a graphite paint or linseed oil."

3. Loads for Highway Bridges

Outer and Inner Forces. A bridge must be designed and built to carry the loads which come upon it. The loads bring into action the supports, or reactions, which, together with the loads, are called OUTER FORCES. The outer forces bring into action certain inner, or fiber stresses, called INNER FORCES. A structure is said to be STATICALLY DETERMINED with regard to the outer forces when the reactions may be found by statics. In general, a structure upon two points of support has the points of application of these reactions known. This leaves the magnitude and direction of each reaction unknown. By placing rollers under one support, or in some way arranging a sliding device, this reaction may be assumed to take no horizontal component and thus its direction becomes known, and leaves only three unknown values. Since there are three statical equations of equilibrium, these values may be found. In the case of a bridge with one end on rollers and all the loads vertical, the problem becomes even more simplified.

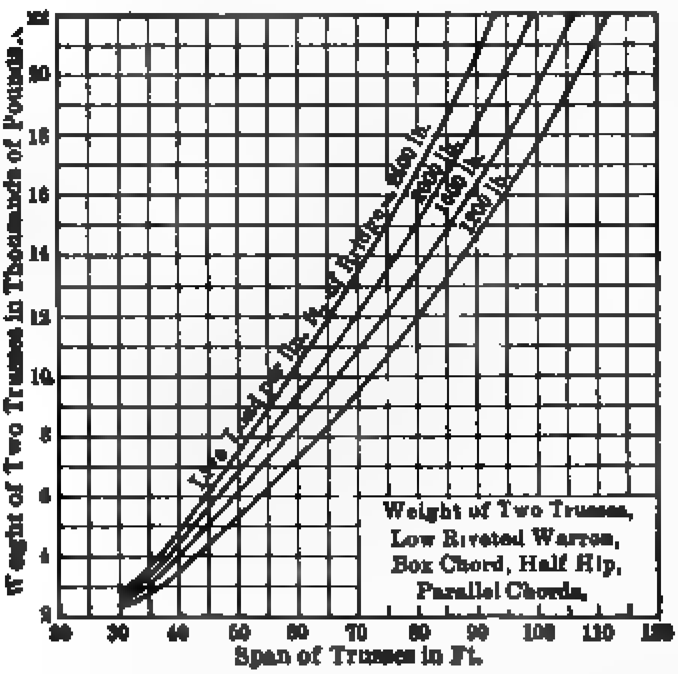

Fig. 1

Loads may be divided into (1) DEAD, (2) LIVE. The dead load is the weight of the bridge. The live load is the load which may be removed from the structure, and may be either fixed or moving, and will vary with the local conditions. It may take the form of a uniformly distributed load such as w lb per lin, or sq ft. It may cover all, or only a portion, of the space. It may also take the form of concentrated loads.

Dead Loads are found by successive approximations; that is, the dead load is assumed, the structure designed, and the weight computed, this computed weight is compared with that assumed and, if found to differ materially, a new weight is taken and the structure redesigned. The weight of a bridge includes (1) weight of metal, and (2) weight of other material, such as flooring. Owing to a greater variation in width of roadway and design in highway bridges than in railroad bridges, formulas will not

Weight of Two Trusses in Thousands of Pounds

Fig. 2

give so close an approximation to the weight of the former as to the weight of the latter.

Figs. 1 to 5, taken from Ketchum's "Design of Highway Bridges" (15a), give the weight of several types of trusses for different span lengths. Fig. 6 gives the weight of lateral bracing, and Fig. 7, the weight of floor beams. In each case, the weight of flooring and stringers must be figured separately and included. By use of these curves, a very fair estimate of dead load may be made.

Fig. 3

Live Loads on a highway bridge may include WEIGHT OF TRAFFIC AND WIND LOAD, IMPACT LOAD, SNOW LOAD, and TEMPERATURE LOADS. The amounts of these loads are given in specifications. The traffic load should be assumed with reference to the location of the bridge, and due regard should be given to future possible conditions. Impact stresses may be treated in one of two ways. The allowable unit stress for live load may be reduced or the live load stress in different members may be increased. This last is obtained by a formula which usually takes the following form.

$$\text{IMPACT} = S\left(\frac{C}{L + C_1}\right)$$

where IMPACT is the impact stress to be added to the live stress, S is the live load stress, L is the length which was loaded to produce the live load stress, and C and C_1 are constants. The weight of SNOW and ICE varies with the latitude and may be taken as 30 lb per sq ft in northern New England, 20 lb per sq ft in latitude of New York City, and 10 lb per sq ft in latitude of Baltimore. The TEMPERATURE LOAD may amount to the reaction multiplied by the coefficient of friction of the rollers. An allowance of 83° C (150° F) requires a space for a motion amounting to ⅛ in for each 10 ft of length. This load is usually negligible in considering stresses in bridge members.

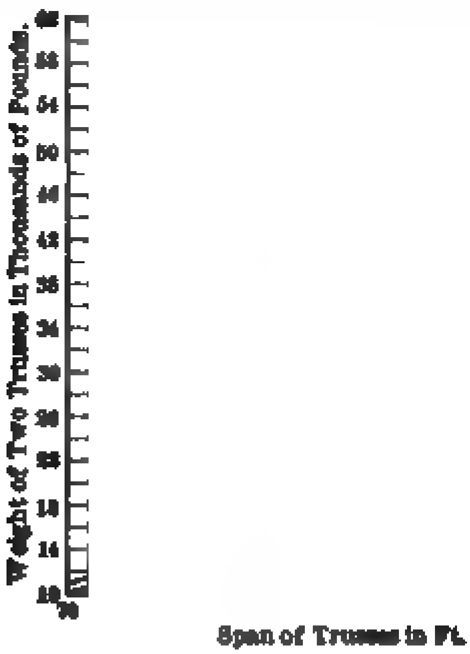

Fig. 4

4. Specifications for Highway Bridges

Specifications for Steel Highway Bridges have been written by various consulting engineers and bridge companies. The following extracts are

taken from the four different specifications given below. The letter after each item shows its source. It should be noted that all except Cooper allow for impact by increasing the live load stresses. Key: C = Cooper, 1909 (Revised by Berger) (8); O = Ostrup, 1911 (19); K = Ketchum, 1914 (15b), M = Mass. R. R. Comm., 1908.

Weight of Two Trusses in Thousands of Pounds.

Span of Trusses in Ft.

Fig. 5

Types. Wooden stringers or rolled beams up to 20 ft, M, O; rolled beams up to 25 ft, C; up to 30 ft, K; rolled beams or plate girders 20 to 30 ft, M; 20 to 40 ft, C, O; plate girders 30 to 70 ft, M; 40 to 70 ft, O; plate or lattice girders 40 to 80 ft, C; plate girders or riveted low trusses 30 to 80 ft, K; 70 to 100 ft, M; 80 to 100 ft, O; lattice girders 80 to 120 ft, C, riveted trusses 100 to 125 ft, M; 100 to 160 ft, O; riveted or pin-connected trusses 125 to 200 ft, M; 80 to 160 ft, K; over 120 ft, C; pin trusses over 160 ft, O, K; over 200 ft, M.

Clearances. Seven feet on each side of track center at heights exceeding 1 ft above top of rail, C, O, K; at heights between 10 in and 12 ft above rail, M; on straight track, and equivalent on curves. Fifteen feet clear above rail, C; same for width of 8 ft above track, M, K; for width 6 ft, O; for country bridges not carrying electric cars 12 ½ ft clear above roadway, C, K, O; for such city bridges 14 ft, O.

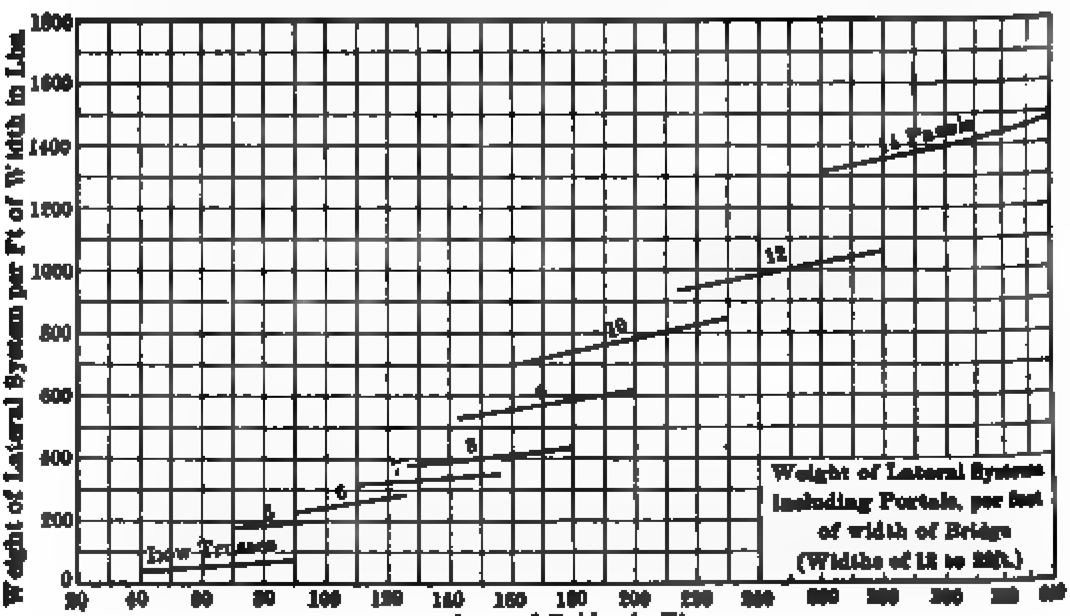

Fig. 6

Classification. COOPER: A_1, city bridges buckle plate floors and paving on concrete base. A_2, city bridges plank flooring: B, suburban or interurban bridges carrying heavy electric cars; C, town or country bridges carrying light cars, or heavy loads from quarries or manufactories; D, country bridges carrying ordinary traffic. MASS. R. R. COMM. AND OSTRUP: A, city bridges subject to heavy loads; B, suburban or

town bridges or heavy country highway bridges; C, light country highway bridges. KETCHUM: A, city traffic; B, suburban or interurban heavy electric cars; C, country, ordinary traffic, light electric cars; D_1, country, heavy traffic; D_2, country, light traffic.

Loads. DEAD. Weight of metal, weight of material other than steel, C, O, K, M; stone blocks 160 lb per cu ft, O, K; paving brick 150 lb per cu ft, O, K; concrete 150 lb per cu ft, K; 130 lb, O; asphalt 130 lb per cu ft, O, K; oak or hardwood 4½ lb per ft, B, M; pine or soft wood 3½ lb, C, O, K; rails, fastenings and splices, etc, 100 lb per lin ft of track, O, K, M; minimum weight of cross-ties and guard rails 200 lb per lin ft of track, O; total weight of floor above stringers not less than 300 lb, M.

LIVE FOR FLOOR SYSTEM. Cooper, classes A_1 and A_2, and Ketchum, class A; a concentrated load of 24 tons on two axles 10 ft center (occupying 12 ft in width for a single line and 22 ft for a double line), and upon the remaining portion of the floor, including footwalks, 100 lb per sq ft. Cooper, class B and Ketchum, class B; a concentrated load of 12 tons on two axles 10 ft center or on each street-car track 24 tons on two axles 10 ft centers, and on remaining portion 100 lb per sq ft. Cooper, class C, and Ketchum, class C; a concentrated load of 12 tons on two axles 10 ft centers, or on street-car track 18 tons on two axles 10 ft centers, and on remaining portion 100 lb per sq ft. Cooper, class D, a load of 80 lb per sq ft total floor surface or 6 tons on two axles 10 ft centers. Ketchum, class D_1; a load of 100 lb per sq ft total floor surface or 20 tons on two axles 11 ft centers and 7 ft gauge, 4/5 of load on rear axles. Ketchum, class D_2; a load of 80 lb per sq ft total floor surface or 15 tons on two axles 10 ft centers and 6 ft gauge, ⅗ load on rear axles. Ostrup; if electric railway tracks occur, a series of 50-ton cars on two trucks 20 ft centers, truck axles 5 ft centers, 5 ft gauge, having total length of 40 ft and width of 10 ft, shall be used in addition to the following: Class A, a load of 20 tons on two axles 8 ft centers, 5 ft gauge, occupying a length of 20 ft and width 10 ft and remaining area 100 lb per sq ft. Ostrup class B; a load of 15 tons on two axles 8 ft centers, 5 ft gauge, remaining area 90 lb per sq ft. Ostrup, class C; a load of 10 tons on two axles 8 ft centers, 5 ft gauge, remaining area 80 lb per sq ft. Mass. R. R. Comm., a 50-ton double-truck car, wheel base 25 ft, wheel base of truck 5 ft, to be used on all classes; also a 15-ton road roller 11 ft center to center of rollers with 6 tons on front and 9 tons on rear and for this condition allowed fiber stresses may be increased 30%. Mass., class A; also 100 lb per sq ft of surface or load 20 tons on two axles 12 ft centers, 6 ft gauge. Mass., class B; also 100 lb per sq ft of surface or load 12 tons on two axles 8 ft centers. Mass., class C, also 80 lb per sq ft of surface.

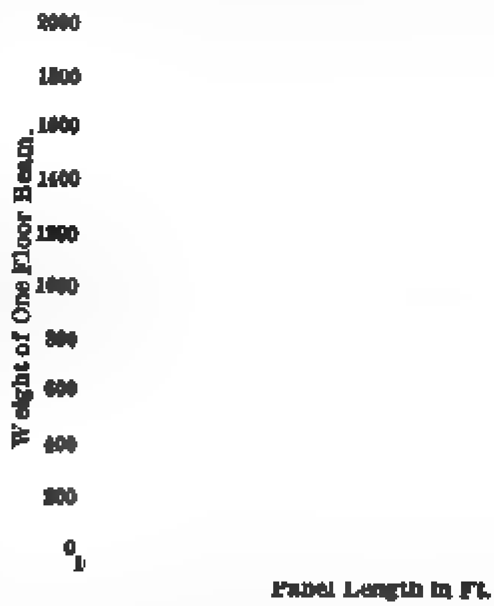

Fig. 7

LIVE FOR TRUSSES. Ostrup, class A: 100 lb per sq ft, spans 100 ft or less; 80 lb, spans 200 ft or over, proportionally for intermediate spans. Class B: 90 lb per sq ft, spans 100 ft or less; 70 lb, spans 200 ft or over. Class C: 80 lb per sq ft, spans 100 ft or less; 60 lb, spans 200 ft or over. In addition to these loadings, a series of cars as afore stated (see FLOOR SYSTEM). Mass. R. R. Comm., class A, same as Ostrup. Class B, same as Ostrup, class C. Class C: 80 lb per sq ft spans 75 ft or less; 50 lb, spans 200 ft or over. In addition to these loadings, a car on each track as stated under floor system, or a uniform load on each track varying from 1500 lb to 1000 lb per lin ft of track.

WIND. 300 lb for each foot of span, 150 lb treated as moving load for top lateral of deck and bottom laterals of thru bridges; 150 lb for each foot span for bottom laterals of deck and top laterals of thru bridges, C, K; in bridges with sway bracing, one-half of wind load assumed to pass to lower chord, K; 50 lb per sq ft exposed

Live Loads for Trusses: Cooper and Ketchum

Span in Ft	Class A		Class B		Class C		Class D_1	Class D_2

200 and over	1 200	80	1 200	60	1 000	60	60	55

NOTE: Cooper, Class D, same as Ketchum, Class D_2.

surface of both trusses, unloaded, 30 lb per sq ft exposed surface structure, loaded, M, O; area of car to be added to area structure, M; when structure is loaded, in addition, 150 lb per lin ft of loaded chord, or 300 lb per lin ft, if carrying electric cars. Minimum 250 lb per lin ft for loaded and 150 lb per lin ft for unloaded chord, O. Centrifugal and longitudinal forces provided for in all.

IMPACT. Allowance in unit stress, C; $I = S \times 100/(L + 300)$, K; same for highway traffic only, O; $I = S \times 200\ /(L + 300)$ bridges carrying electric railways, O; I = impact, S = computed live load, L = loaded length in feet. The following percentages of live load are given by M: Floor beams and stringers, 25; floor beams and hangers, 40; counters, 40; other members in trusses and main girders when loaded length is 20 ft or less, 25; when loaded length is 200 ft or more, 10.

Allowable Stresses in lb per sq in.

TENSION. Axial, on net section, 16 000, K, O, M; floor beam hangers, 8 000; sway bracing, lateral forces, 18 000; sway bracing live load, 15 000; solid rolled beams, 13 000; bottom flanges, plate girders, chords, webs of trusses, 12 500 live, 25 000 dead, verticals carrying floor beams, 10 000 live, 20 000 dead, C.

COMPRESSION, axial gross section, $S = 16\ 000 - 70\ L/r$, O, K. S = allowable unit stress; L = unsupported length, inches; r = least radius of gyration, inches

$$S = \frac{12\ 000}{1 + \frac{1}{20\ 000}\frac{L^2}{r^2}}\ \text{M.}$$

Chord segments, $S = 12\ 000 - 55\ L/r$; posts of thru bridges, $S = 10\ 000 - 45\ L/r$; posts of deck bridges, $S = 11\ 000 - 40\ L/r$. For dead load, use twice these values. Lateral struts and rigid bracing, $S = 13\ 000 - 60\ L/r$, C.

Bending extreme fibers rolled shapes and built sections 16 000, K, O; extreme fibers, pins, 24 000 K, O, M; pins 20 000, C.

Shearing, plate girder webs, gross section 10 000, K, O; pins and shop rivets 12 000, K, O; 10 000 except 8 000 for floor system and 15 000 for laterals, C; 11 000, M; field rivets, allowable stress reduced 33.3%, C; 10 000, K; when power driven 11 000, hand driven 9000, O; when power driven reduce allowable stresses 10%, hand driven 25%, M.

Bearing, pins 15 000 live, 30 000 dead, C; 22 000, M; 24 000, K, O. Shop rivets 18 000 except 14 400 for floor beams and 27 000 for lateral, C; when area is enclosed between other pieces 20 000, not enclosed 18 000, M. 24 000, K, O. Field rivets reduce allowable stress 33.3%, C; 20 000, K; hand driven 18 000, power driven 22 000, O; reduce allowable stress hand driven 25%, power driven 10%, M.

Bed Plates and Rollers, bearing on masonry 250 lb per sq in, C; 400, M; 400 to 600, K, O. Bearing on expansion rollers in lb per lin in 300 *d*, C; 600 *d*, M, O, K; *d* = diameter of roller in inches.

Details of Design and Construction.

Proportion of Parts. Alternate Stresses: Members subject to alternate stresses shall be proportioned to resist each; increase both stresses by 30% of least of two stresses; rivets and bearing areas on pins increased 50% over usual, C; proportioned to resist maximum of each kind, but unit stress is less than stress of one kind, as follows; if the two maximum stresses are same, unit stresses are ½ above tension and compression for live; if smaller is ½ larger, unit stresses are ¾ of above tension and compression for live and proportionally for other ratios, M; proportioned for stresses giving largest section. If stresses occur in succession, increase each by 50% of smaller: connections proportioned for sum of stress, K. Members subject to reversal of stresses shall be proportioned for equivalent stress equal to that stress which, when added to 50% of the other, will give the greater section, both impacts added, O.

Counters: Area found by taking difference areas due to live and dead stresses separately, C, so that future increase in live load of 25% will not increase stress more than 25%, C, K.

Combined Stresses: Members subjected to both axial and bending stresses shall be designed so greatest fiber stress shall not exceed allowable unit stress, K, C; if fiber stress due to dead weight of member exceeds 10% of its allowable unit stress, such excess must be considered, C, K; stresses from assumed wind loads not considered unless unit stress is greater than 30% of live and dead unit stresses (in which case section increased until unit stress does not exceed by more than 30% of the maximum fixed for live and dead) or unless wind and temperature stresses reverse stress, C; 25%, K; members receiving stress from vertical loads and from lateral or longitudinal forces, unit stress shall not exceed allowable by more than 25%, M. When combining stresses due to vertical forces with those due to lateral forces, including direct and indirect wind and bending due to wind, unit stresses may be increased 25% if this gives a greater area, O. When both direct and flexural stresses due to wind are considered, 50% may be added to allowable stresses for dead and live provided the area is not less than required for dead and live alone, or for dead, live, and direct wind, K.

Riveted Tension Members: Net section thru pin hole 33.3% net section of member and back of pin hole at least 60% of net section thru pin hole, C; same except 25% and 75%, M, K; same as M except minimum section back of pin hole equals that thru body of member, O.

Plate Girder Flanges: Flanges carry all moment, web, all shear, C; ⅛ gross section web used as flange section if properly spliced, K, M, O; gross area tension and compression flanges equal, C, M, K, O; compression flange braced at distance equal to 16 times width, C; 12 times, O; 12 ft, K; if not braced at distance 20 times width allowable stress reduced, M; 40% flange area in angles, O; 50%, C; flange plates to extend beyond their theoretic length 2 rows of rivets at each end, C, M; 12 in O; flange plates not to extend more than 5 in or more than 8 times thickness of thinnest plate beyond outer line of rivets, C, M.

Plate Girder Webs: Net section carry total shear, M; gross section carry total shear, O; minimum thickness 5/16 in, K, C, M; not less than 1/160 unsupported distance between flange angles, O, K.

STIFFENERS: Webs to be stiffened at bearings and concentrated loads and at intervals not to exceed depth girder or 5 ft; whenever shearing stress in web exceeds 12 500 − 90 h/t, where h = depth and t = thickness web, inches, C, K; wherever shearing stress exceeds 12 000 ÷ [1 + (d^2 = 3000 t^2)] where t = thickness web, inches, and d = clear distance, inches, between flange angles, M; allowable stress in stiffeners 16 000 − 70 L/r, K, O; 12 000 − 55 L/r C;

MINIMUM THICKNESS OF METAL: 5/16 in main members, 1/4 in laterals, C; 5/16 in classes A, B and C, 1/4 in classes D, and D., K; 5/16 in, 1/4 in for channel webs, O, M; over steam railroad 3/8 in below floor, M.

COMPRESSION MEMBERS: L/r not more than 100 except laterals 120, M, C; same except 125 and 150 for classes D_1 and D_2, K; 120 and 140, O; abutting joints when faced for bearing, shall be spliced four sides to keep members in place, all other joints in riveted work to be fully spliced, C, K, O; all joints in riveted work fully spliced, M; unsupported width (between rivets) of cover plates not to exceed 30 times their thickness except cover plates, top chords and end posts which are limited to 40, C, K; 48, O; pitch of rivets not to exceed 4 diameters of rivet for length equal to twice width of member, C, M, O; and for length equal 1 1/2 times width, K; when necessary pin holes shall be reinforced by plates, K, O, M, C.

BATTEN PLATES: Placed near ends of compression members, length not less than greatest width member or 1 1/2 times its least width, C, K; length not less than greatest width and thickness not less than 1/50 distance between connecting rivets, M; not less than width of member, minimum 10 in, O.

LATTICING: Thickness not less 1/40, for single bars and 1/60 for double bars riveted at intersection, of distance between rivets connecting them to member, M, K, O, C; minimum of 5/16 in, M; width not less, for 15 in channels or built sections with angles over 3 in, than 2 1/2 in, M, O; for 12, 10, 9, 8, and 7 in channels, 2 1/4 in, M; 12, 10, and 9 in, 2 1/4 in, 8 and 7 in, 2 in, 6 in or less, 1 3/4 in, O; 18 in and over, 2 1/2 in, 15 in, 2 1/4 in, K; 2 1/2 in, C; 12 in, 2 in, K; 2 1/4 in, C; 9 in 1 3/4 in, K; 2 in, C; 6 in, 1 1/2 in, K; 1 3/4 in, C; single latticing inclined not less than 60° to axis member, double latticing, 45°, C, O, M, K.

RIVETS: Minimum pitch 3 diameters of rivet, maximum 6 in or 16 times thinnest outside plate connected, C, O, M, K; distance from edge never less than 1 1/2 or 2 diameters of rivet, C, M; for 7/8 in rivets, 1 1/2 in; 3/4 in rivets, 1 1/4 in; 5/8 in rivets, 1 1/8 in; from sheared edge and from rolled edge 1 1/4 in, 1 1/8 in and 1 in respectively, O, K; not more than 8 times thickness plate, M, O.

ROLLERS AND BOLSTERS: Spans 80 ft and over, resting on masonry, to have turned rollers or rockers at one end, less spans to have one end sliding, K, O, M; 100 ft and over, C; rollers 3 5/8 in diameter for spans 100 ft or less; increase 1 in for each 100 ft additional, C; same save for 100 ft or less diameter 3 in, K; in any case not less than 3 in; not less than 4 in, O; spans 80 ft or over have hinged bolsters at each end, O, M; 100 ft or over, C.

CAMBER: All bridges to be cambered by giving panels of top chord an excess length of 3/16 in in 10 ft, C, K; 1/8 in in 10 ft, M, O.

FLOORS. Floor beams shall be rolled or riveted steel girders, rigidly connected to the trusses at the panel points, C, K; may be placed on top deck bridges at panel points, K; all longitudinal girders of bridges classes A_1 and A_2, all track stringers classes B and C will be steel; unless otherwise specified, all other longitudinal girders classes B and C will be of steel; all longitudinal girders class D shall be either steel or wood, C; all joists and stringers classes A and B shall be of steel, joists for classes C, D_1 and D_2 either wood or steel, K; steel stringers shall be securely fastened to cross floor beams, C, K; width of wooden joists not less than 1/4 depth or 3 in, C, K; wooden joists not spaced over 2 ft centers and will lap by each other so as to have a full bearing on the floor beams, will be separated 1/2 in for free circulation of air, C; same except 2 1/2 ft centers, K; when spaced 2 ft centers, one joist to be considered carrying only 3/8 concentrated live load, C; same except 1/2, K. For single thickness, floor plank shall not be less than 2 1/2 in thick for oak or 3 in for pine, nor less than 1/12 the distance between centers of joists, laid transversely with 1/4-in openings; for additional wearing surface use a thickness of 1 1/2 in in which case lower plank 2 1/2 in thick shall be laid diagonally, K. Floor plank to have thickness in inches at least equal to distance apart of beams in feet or a minimum of 2 1/2 in, C. Footwalk plank 2 in thick and not more than 6 in wide with 1/2 in openings, C, K; in city bridges with buckle plate

floors, buckle plates not less than 5/16 in thick and crown not less than 2 in, C, K; bridges with buckle plate floors shall have suitable metal curb on each side of roadway to hold paving and act as wheel guard; wheel guard so arranged that it may be removed and replaced when worn or injured; there will also be a metal edging strip on each side of footway to hold paving in place, C; same except curb may be stone or steel, K; concrete over buckle plates at least 3 in thick on roadway and 2 in on sidewalks, C, K.

5. Shears and Bending Moments in Beams and Trusses

Altho this subject belongs in the part of Sect. 2 dealing with MECHANICS, and is there explained in principle, it appears necessary to show its application to beams and trusses. Notation: w = uniform load per foot, L = length of span; x = distance from left reaction to section considered; R_1 = left reaction; R_2 = right reaction.

Vertical Shear is the algebraic sum of the vertical forces on either side of a section. If upward forces are called plus and downward forces minus, the algebraic sum on one side of a section in a structure in equilibrium must be equal to and of opposite sign from that on the other side, since $\Sigma V = O$. The sign of the shear is arbitrarily fixed as positive when upward on the left and downward on the right of a section. In order to find the shear, it is therefore necessary to find all of the vertical forces on one side of the assumed section. In general, choose the side which requires the lesser work. In beams which are free at one end, work from the free end.

Bending Moment at a section is equal to the algebraic sum of the moments of the forces on either side of the section about an axis in the section. The sign of the bending moment is usually called positive when the algebraic sum of the moments on the left of the section is clockwise. In a beam on two points of support, a positive moment causes compression in the top fibers and tension in the bottom fibers. The sum of the moments of the forces on one side of a section will have the same numerical value, but the opposite direction, as the sum of the moments of the forces on the opposite side.

Curves of Shear and Moment. If the value of the shear, or moment, is found for different points thruout the length of the beam for some fixed loading and these values are plotted and connected by lines, the resulting curve is called the CURVE OF SHEARS, or the CURVE OF MOMENTS. Such a curve is of assistance in showing graphically where the maximum and minimum values of these functions occur. It will be noticed that at the point where the shear passes thru zero, the moment will be a maximum.

Influence Lines. An influence line shows the effect of a load of unity passing over the structure, at some particular section, on some particular function such as shear, moment, or stress. It is constructed for a load of unity, and for a particular section. As the load of unity passes over the structure, the value of the function under consideration is plotted below the load, thus forming a curve, the ordinate to which at any point is the value of this function, at the section assumed, due to the load of unity over the ordinate. It is oftentimes used to study the position of the loading which will give a maximum or minimum of the function under consideration.

Two General Cases must be considered for both shear and bending moment. Case 1. BEAMS WITHOUT FLOOR BEAMS. Case 2. BEAMS WITH FLOOR BEAMS. Each of these cases must be considered for both DEAD LOAD and LIVE LOAD. Case 1 includes the conditions of loading usually applied to the stringers of any bridge, while case 2 includes the condi-

tions usually applied to the girders or trusses when floor beams are used. Altho case 2 is made to include concentrated or wheel loads, it should be noted that the stresses in the trusses or girders of highway bridges are usually found by considering a uniform live load which may be reduced to concentrated panel loads, and applied at the panel points. When such loadings are used, the rules for finding the position of the loads to give a maximum moment or shear are simplified as indicated.

Case 1. Shear with Dead Loads. In a beam on two points of support fully loaded with a uniform load, R_1 is $\frac{1}{2}\, w\, L$ and the shear at any section will be $\frac{1}{2}\, w\, L - w\, x$. At the center of the beam this becomes zero. To the right of the center it is negative. At an infinitely small distance to the right of R_1 the shear will be a maximum with a positive sign and will equal R_1. In case the uniform load does not cover the entire space, and only extends a distance b from the left end, R_1 will equal the value given by the formula for R_1, and the shear at any section will equal R_1 minus the load from R_1 to the section in the same manner as before. At an infinitely small distance from R_2 the shear will be a maximum with a negative sign and will equal R_2. In case concentrated loads are upon the span, R_1 is found due to these loads and the shear at any section is equal to R_1 minus the loads between R_1 and the section. The total shear for both uniform and concentrated loads is the sum of each shear found as indicated above.

$$R_1 = \frac{w b\left(\frac{b}{2} + L - b\right)}{L},$$

Case 1. Bending Moment with Dead Loads. In a beam on two points of support fully loaded with a uniform load, R_1 is $\frac{1}{2}\, w\, L$ and the moment at any section is $\frac{1}{2}\, w\, L\, x - w\, x^2/2$. At the center of the beam, the moment is $\frac{1}{4}\, w\, L^2 - w\, L^2/8 = w\, L^2/8$. The moment at each end of the beam is zero. The maximum moment comes at the center and the curve of moments is a parabola, with its origin at the highest point and axis vertical. The sign of the moment is positive thruout the span. In case the uniform load does not cover the entire span find R_1, as in the case explained for shear, the moment will equal $R_1 x$ minus the moment of the uniform load, between R_1 and the section, about the section. In case concentrated loads are upon the spans, R_1 is found due to these loads and multiplied by the distance to the section, and the moments of any loads coming between R_1 and the section subtracted therefrom. The total moment for both uniform and concentrated loads is the sum of each moment as indicated above.

Case 1. Shear with Live Loads. A live load may be either uniform or concentrated. To find the maximum positive shear at a section X, the load is moved on the structure from the right up to the section. The shear will equal R_1. To find the maximum negative shear move the load on from the left up to the section and the shear will equal R_1 − load, or R_2. In order to find the maximum positive shear due to concentrated loads, the position of the loads causing a maximum must first be found. In Fig. 8, let $P_1 + P_2 + P_3 + P_4 = P$. Move up the system until P_1 is at the section. The shear is now equal to R_1. Now move the system until P_2 is at the section. The shear will be increased provided the increase in R_1 is greater than P_1, which must now be subtracted from R_1 to obtain the shear under this last loading. In general, move up the loads until a position is found where the increase in R_1 becomes

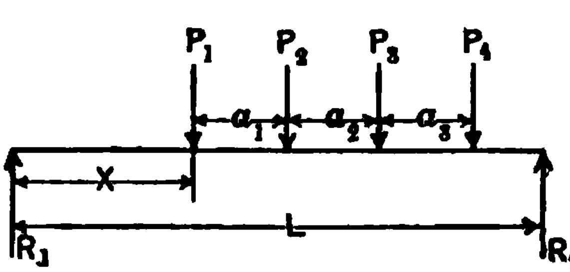

Fig. 8

less than the sum of loads to the left of section, and then move the system back to the right until the next load to the left is at the section. It may become necessary to consider the effect of a new load which may come on the span from the right, or a load which may leave the span on the left, provided such a condition occurs during the operation of moving from the load at the section to the next one. The maximum end shear will be equal to the maximum R_1 which can be obtained. It will usually occur when a heavy load is over R_1 and the other loads as near as possible. In general, begin by placing a heavy load at R_1 and move up the system so that the next load will come at this point. The end shear will be increased by so doing, provided that the increase in R_1 due to moving up the entire system is greater than the load first placed at R_1, which is now moved off. Proceed until the opposite condition is found and then move back to the right until the next load to the left is over R_1.

Case 1. Moment with Live Loads. The position of the loads for a maximum must first be determined. In general, the average load on the right of the section must be equal to or greater than the average load on the left. With a uniform load it can be placed so that $w/(L - x) = w/x$. In the case of one concentrated load, it should be placed at the section. In the case of several concentrated loads, the method of moving up the loads is to be used, first placing some heavy load at this section. In applying the above rule, always consider the load at the section as being in the sum on the right. Move up the loads until a load is found which, when considered in this sum, gives the average on the left greater than the average on the right, and then move the system back one load toward the right. Find the moment under this load. In a long series of concentrated loads, several positions may be found which will satisfy the rule. In general, the moment must be calculated for each and the largest result taken.

Absolute Maximum Moment. This applies to beams without floor beams only. The section where the largest moment due to concentrated loads occurs is not known. From mechanics it is shown that the bending moment is a maximum when the shear passes thru zero, but this point changes position with the moving loads. In general, this section will be as far from one end of the beam as the resultant of all the forces is from the other. In applying this rule, find, by the rule in the previous paragraph, the load which gives a maximum moment at the center of the beam. Find the position of the resultant of all the loads on the structure and move the loads so that the load which gave a maximum at the center is as far from the center on one side as the resultant is on the other. See if shear passes thru zero at this load and if so, find the moment under it. Due consideration must be given to any loads which pass on or off the beam in the process of placing the resultant on one side or the other of the center of the beam.

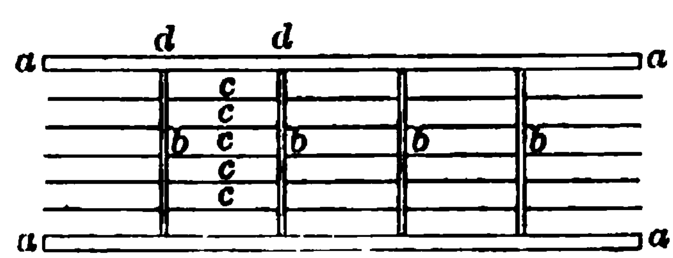

Fig. 9

Case 2. Shear with Dead Loads. In order to understand the action of floor beams upon shear and moment, the path by which the loads are conducted to the reactions must be fully comprehended. Fig. 9 shows the arrangement of the floor of a highway bridge: *aa* represents the girders or trusses; *bb*, the floor beams; *cc*, the lines of stringers, and *dd*, the

panel points. The load is first taken from the plank floor of the bridge to the stringers and then by the floor beams to the girders and by them is transmitted to the reactions. It may thus be seen that no load can be applied directly to the girders between floor beams except its own weight, as any load coming on the floor between must be distributed by the stringers to adjacent floor beams. The shear will then be constant between panel points for any particular loading. The shear in a panel as ab, Fig. 10, due to a uniform dead load will be $R_1 - w\,a_1 - w\,p/2$. In other words, not only the load to the left of a must be subtracted from R_1 but also the panel reaction at a due to the load in the panel.

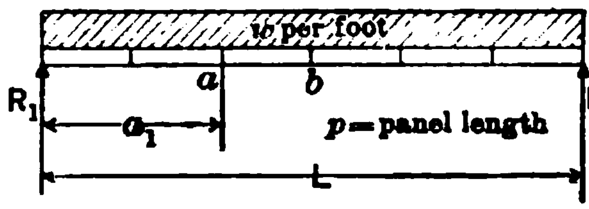

Fig. 10

CASE 2. MOMENT WITH DEAD LOADS. In Fig. 11, a, b, c shows the curve of moments for a beam without floor beams, while a', b', c' shows the curve for the same span introducing the floor beams. It may be seen that the moments for both curves are the same at the panel points and that between panel points the moments with floor beams are less. Find the moments at the panel points in the same manner as in CASE 1, UNIFORM LOAD.

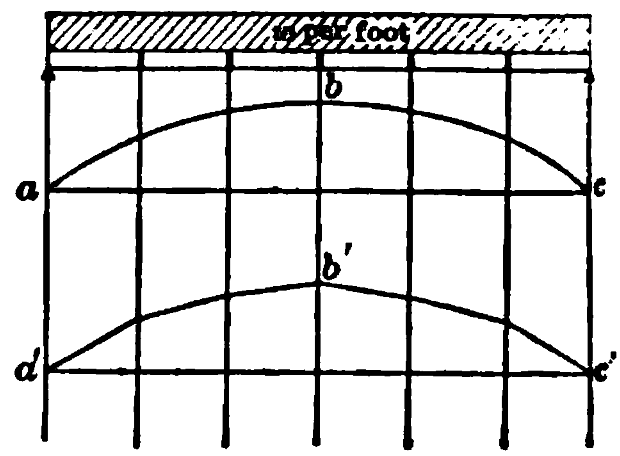

Fig. 11

CASE 2. SHEARS WITH LIVE LOADS. To find the maximum positive shear in any panel with a system of concentrated loads, the loads are moved on from the right up to the panel considered. In general, with the usual loads, no loads will pass beyond the panel. Move the loads up, always considering the load at the panel point to be included in the sum to the right, until a position is found where the average in the panel is greater than the average to the right and then move back to the previous position and calculate the shear in the panel. For highway bridges where panel concentrated loads are usually applied only at the panel point, this rule reduces to loading all panel points to the right of the panel considered.

CASE 2. MOMENTS WITH LIVE LOADS. This condition reduces to CASE 1 as the moments at the panel points are the same as if no panels existed. If, however, panel loads are used, load each panel point to obtain a maximum moment at any panel point.

The Maximum Floor Beam Reaction is the largest reaction which can be obtained in any floor beam and is found by loading the stringers on each side of a floor beam as heavily as possible. In the case of a uniform live load, the entire floor and sidewalk, if any, between two floor beams is loaded and the amount carried by each stringer to the floor beam is calculated. The reaction of the floor beam due to these loads is then found. The dead load of the floor covering and weight of stringers is also found and concentrated on the floor beams at the stringer connections from which, together with the weight of the floor beam itself, the dead reaction may be found. In case it is necessary to investigate also for concentrated loads (see Art. 4, LIVE LOAD), such as heavy teams, electric cars, road rollers, etc, the problem becomes more complicated. For this condition, place the concentrated loads so that one axle will be over

the floor beam and, taking into account the space occupied, load the remainder with uniform load. Then find the reaction of all stringers which support the load and this will give the amounts transmitted to the floor beam. Lastly, find the reaction of the floor beam due to these concentrations.

6. Steel Highway Bridges

Rolled Beams of steel are made in various shapes, the two most common being the I-beam and the channel. Properties of these shapes may be found in the various steel handbooks, see (6) and (7). Beams are designed by the formula $M = SI/c$ where M is the maximum moment in inch-pounds, S is the allowable unit value of the material, I is the moment of inertia of the section about its neutral axis, and c is the distance from the neutral axis to the extreme fiber. In this formula I/c is constant for any given beam and is tabulated as SECTION MODULUS.

EXAMPLE. **Design a steel I-beam 16 ft long to carry a load of 300 lb per ft which includes the weight of the beam. Allow a fiber stress of 10 000 lb per sq in.**

$M = \frac{1}{8} \times 300 \times 16 \times 16 \times 12 = 115\,200$ in lb.

$M/S = I/c = 11.5$. **From CARNEGIE we find a 7 in 17.5 lb I has a section modulus of 11.2, and an 8 in 17.5 lb I, a modulus of 14.6. Either of these would probably do, but the latter would give a greater strength for the same weight per ft.**

Beam Bridges are bridges made up of I-beams or channels, or both, with their ends resting on abutments (see Fig. 12). The number of beams necessary depends upon the loading and they are usually from 2 to 3 ft apart. Spiking pieces are bolted on the top of each beam to which the plank flooring is spiked. A spacing of 3 ft would call for a plank flooring of about 3 in in thickness. The maximum economical length of such bridges is from 25 to 30 ft. Wooden railings may be used, altho iron pipe is to be preferred. In designing such a bridge, after the span length is found, the loading which applies to the probable traffic is taken from the specifications and the maximum moments on the stringers computed by the methods explained in Art. 5. After finding the moment, the I-beam may be designed as in the preceding example. In general, the side stringers will not receive as much load as those between them and may be made of channel sections which are designed in the same manner as in the case of the I-beams. In loading for maximum live load shear and moment, it is allowable, when considering concentrated or wheel loads, to assume that each stringer takes only ⅜ of the load directly above it, provided the floor plank is continuous.

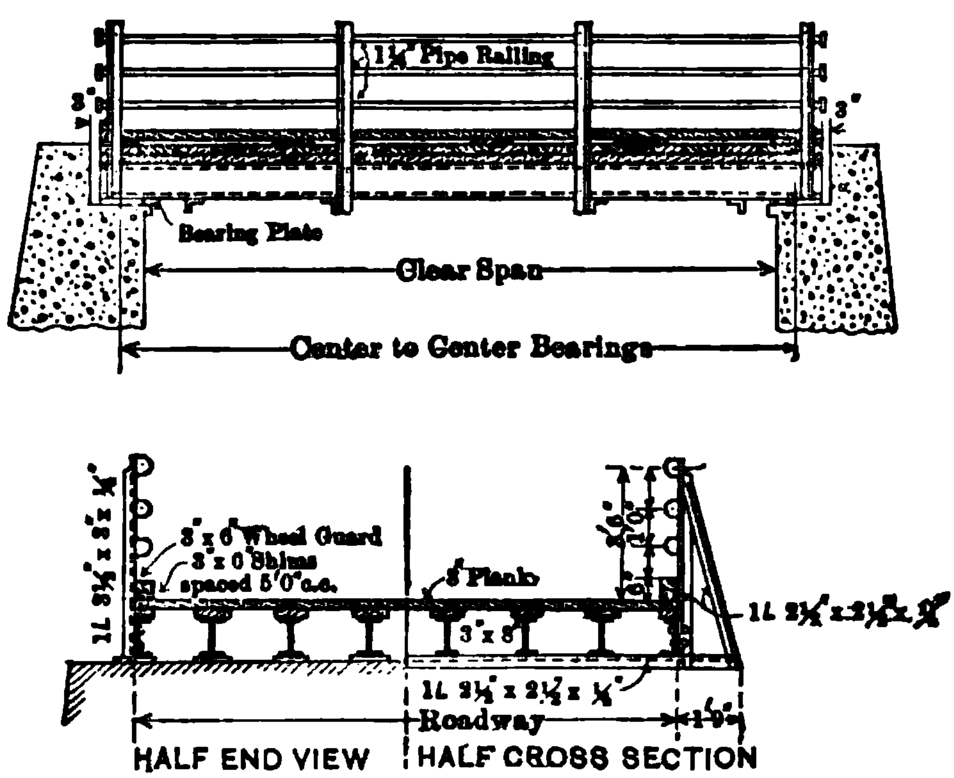

Fig. 12

Girder Bridges are usually of the plate girder type with the general arrangement as shown in Fig. 9. The stringers and floor beams are usually

made up of I-beams altho in some cases, it may be necessary to use built beams for the floor beams. The plate girder is a built beam and is made up of the WEB and FLANGES. The flanges are composed of angles, or angles and plates. A plate girder bridge may be either deck or thru. Unlike a railroad deck bridge, both kinds require stringers and floor beams, the principal difference being that in the deck highway bridge, the floor beams are placed with the tops higher than in the thru bridge. For ordinary traffic, two girders are required, while for heavy city traffic, including heavy electric cars, three or even four girders may be necessary, in which case a deck bridge should be used, if possible, in order to allow a clear roadway. The stringers of a plate girder bridge are designed in a manner similar to that explained for beam bridges. The floor beams, if made up of I-beams, may be selected in a manner similar to the stringers by finding the maximum moment, remembering that the live loads can only be applied at the stringer connection. If made up of built beams, the same general principles to be explained for the design of the girders, which are heavier built beams, will apply. Remember that the floor beam, unlike the girder, is a beam without panel points, and the rules for maximum shear and moment should be applied accordingly. In the design of the girders, the rules for moment and shear applied to CASE 2 apply. In designing a girder, the web is assumed to carry the shear and the flanges the moment. Hence, with the loading assumed, the maximum shear is obtained in each panel and the maximum moment at each panel point up to the center of the bridge.

Stiffeners. As the combined action of the horizontal and vertical shear tends to buckle the web, stiffeners are usually required to prevent this action. These are in the form of angles in pairs riveted vertically to each side of the web. It is the usual practice to provide two pairs of stiffeners at each end, the distance apart being a little less than the bearing plate directly under them. The distance apart of intermediate stiffeners differs slightly according to the various authorities. Cooper recommends that this distance shall not be greater than the depth of the girder with a maximum distance of 5 ft whenever the shearing stress per sq in exceeds the stress allowed by the formula, allowed shearing stress = 12 500 − 90H, where H = ratio of depth of web to its thickness. Cooper also recommends that all stiffeners, both end and intermediate, shall be capable of carrying the maximum vertical shear without exceeding the allowed unit stress as given by the formula, $S = 12\,000 - 55\,L/r$, where S = allowed unit stress; L = length of stiffener; r = radius of gyration of angles at right angles to the web, neglecting inclosed portion of fillers and web. Ketchum also gives the above formula for allowed shearing stress, but for the cross-section of the stiffener recommends the following: $S = 16\,000 - 70\,L/r$, where, in this case, L is one-half the depth of the girder. All stiffeners should connect to the webs by enough rivets to transfer the shear to or from the webs. End stiffeners and those under concentrated loads should be placed upon fillers and should have their ends fitted to the flange angles. Intermediate stiffeners may be placed upon fillers or crimped. In the latter case, this allows the stiffeners to rest directly against the web and at the flange angles it is bent or crimped to fit over these angles.

The Economic Depth of built beams used as girders is usually about from 1/8 to 1/10 of the span length. For short beams which carry the load directly, such as stringers when used with heavy loading, the depth

should be more, and for long girders it is usually taken from 1/10 to 1/12, with a maximum depth of about 10 ft on account of shipping.

The Design of the Web, having assumed the depth, consists of taking a plate of cross-section sufficient to withstand the vertical shear. If V = vertical shear, S_s = the allowable shearing value for web plates and A = the area required, then $A = V/S_s$. As there is usually a line of rivet holes near the section of maximum shear, the available net area will be approximately $\frac{3}{4}th$ where t is the thickness and h the height. Then $\frac{3}{4}th = V/S_s$. It is usual in girders designed under ordinary conditions to make the web of uniform cross-section thruout the span length. The minimum thickness of webs for highway bridges is 5/16 in. In many cases this requirement will call for webs which have an excess of metal.

Design of the Flanges. See Fig. 13. The flanges may be designed either by the moment of inertia of their net section or by assuming that the flange

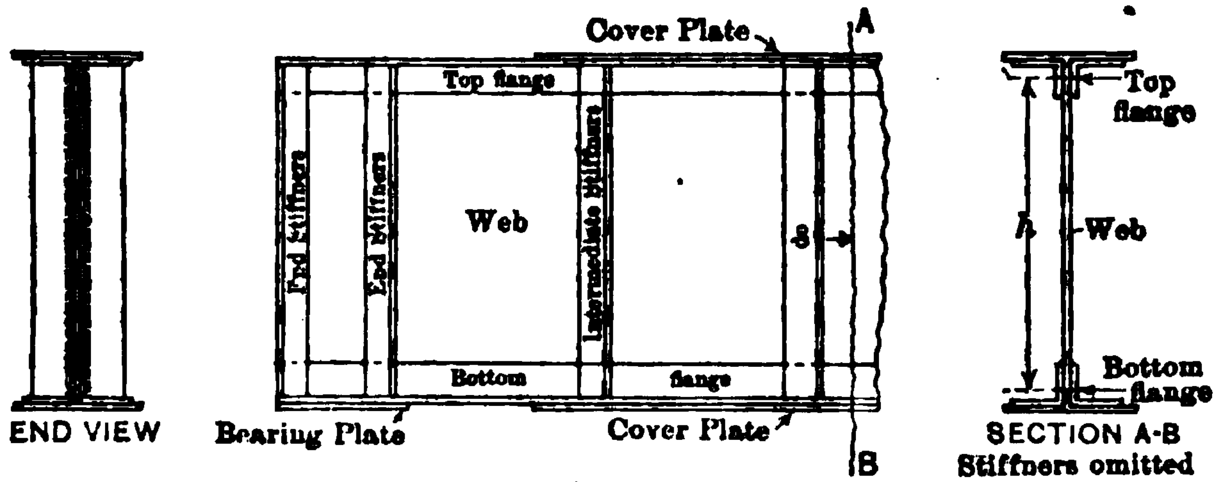

Fig. 13

areas are concentrated at their centers of gravity. The latter method is probably the more common. The flanges are assumed to carry the bending moment. This does not change the fact, however, that a portion of the moment must be borne by the web, and some specifications allow a reduction in required flange area due to this fact. If the latter method is used, it is common to allow ⅛ of the gross area of the web for flange section. If h is the distance between the centers of gravity of flanges, and M_r the resisting moment of the beam, P the total stress in each flange, then $M_r = P\,h$. As the resisting moment must equal the bending moment, $M = P\,h$ or $P = M/h$. Total area A required for one flange will equal P/S where S is the allowable unit stress. If the web is assumed to carry its share of the moment, ⅛ of its area is subtracted from the total area as determined above. The tension flange is usually designed first and the same section used for the compression flange, but the latter must be stayed against transverse crippling at a distance apart not to exceed from 12 to 14 times its width. In case this is not possible, it must be designed as a column by applying a column formula which will reduce the allowable unit stress depending upon the values of its length and radius of gyration, the latter taken about a vertical axis. In making up the section of a plate girder, it is a common requirement that at least ½ the area of the flange section shall be angles or else the largest size of angles shall be used. Other authorities require 40% to be in the angles. The remainder of the area, whichever method is used, is in cover plates. Also the width of the cover plates are limited so as not to extend beyond the outer line of rivets, which connect them to the angles, more than 5 in or more than eight times the thickness of the first plate. Where two or more plates are used as cover

plates, they shall be of the same thickness or else they shall decrease in thickness outward from the angles.

Rivet Spacing in Flanges. Let V_h = horizontal shear per lin in; V = total vertical shear at point considered; Q = statical moment about neutral axis of the portion outside of the section upon which the horizontal shear is to be obtained; I = moment of inertia of whole section of girder about neutral axis, and h = distance between centers of gravity of flanges. Then $V_h = VQ/I$. Various approximations are used for this exact expression, the most common of which is $V_h = V/h$. To obtain the rivet spacing in the vertical legs of the flanges, find the vertical shear at various points and from these find the horizontal shear as above, usually using the approximate formula. Divide the rivet value by the horizontal shear and make the spacing equal to or less than the quotient. This spacing is the distance between center of rivets measured horizontally. In built stringers, compute the horizontal shear at two or three points between end and center; in deck girders, every 2 to 6 ft. Vary the spacing to merge from one result into another. In thru girders, as the live vertical shear is constant between panel points, the maximum dead shear may be added and the spacing be made uniform in each panel. It is, however, a general rule that in no case shall the spacing of rivets be less than three diameters of the rivet or more than 6 in. In the case of beams used as stringers covering concentrated loads, the rivets carry a direct vertical shear in addition to the horizontal shear, and in such cases the resultant shear is the one to be used with the rivet value to find the rivet spacing. To obtain this resultant shear, assume that the concentrated load, coming over the point under consideration, is being transmitted thru the flooring and into the beam and extends over a distance of 3 ft. Then the square root of the sum of the squares of 1/36 of concentrated load and the horizontal shear per linear inch will give the resultant shear per unit. The rivet spacing in cover plates is usually made the same as that figured for the vertical leg, altho, if thought necessary, it may be obtained in a similar manner to that already explained.

Cutting off Flange Plates. Two methods may be used, the analytical and the graphical. In the first, since A, the area required = M/Sh, an expression may be written for M at any point in terms of X, the distance from left support, and this put equal to $A_1 hS$ in which A_1 is the flange area minus the top plate. Solving for X, the distance from the end reaction to a point where the top plate is not required is obtained. Apply the method as many times as there are plates, A_2 being the flange area minus two plates, etc. This method can only be used where an expression for M may be easily written.

In the graphical method, lay off to some convenient scale at the proper points on a straight line perpendiculars which represent the flange area required at each point (see Fig. 14). In the case of a thru girder, these points will be the panel points and the diagram will be drawn for the net area required in the bottom flange at these points. The area will be determined by $A = M/Sh$ where M is the moment at the particular panel point.

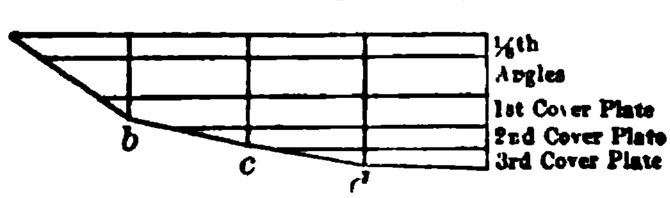

Fig. 14

Connect the ends of these perpendiculars by a curve or a broken line, remembering that the moment varies uniformly between panel points for all except the dead weight of the girder. Measure off on a perpendicular

at the center to the same scale as before, (1) ⅛ area of web, if used, (2) net area of flange angles, (3) net area of the several plates. Draw thru these points horizontal lines and the intersection of these with the broken or curved line will show the points where the several plates may be cut off. Each plate should, however, be extended about 1 ft beyond the point, and it is usual to run the bottom plate of the top flange to the ends of the girder.

Flange Splicing. When the length of the girder exceeds about 60 ft, the flange angle and plates should be spliced. The splice angle or splice plate should contain the same net area as the angle or plate to be spliced, and should have rivets enough to develop the section spliced, that is, to carry the stress value out of the cut member into the splice piece and back into itself again. Where there are several plates in a flange, cut off according to the method as explained, splices for the longer plates are frequently made by increasing the length of the plate on top of it a sufficient distance for a splice plate and cutting the plate to be spliced underneath. As a splice is considered to be a point of weakness, they should be distributed, that is, flange angles should not be spliced at the same section. It is customary to splice them on opposite sides of the center.

Web Splicing. When a web plate can not be obtained of a length equal to the span of the girder, it must be spliced. For lengths of plates, see the various steel handbooks. The splice is made by two plates, one on each side of the web. If the web is assumed to take a part of the moment, it must be spliced for both shear and moment. If all the moment was assumed by the design to be taken by the flanges, then the splice need be made for shear alone, altho some authorities claim that the web should always be spliced for moment and that in many cases under this condition shear may be neglected. In either case, it is first necessary to assume a splice with say two rows of rivets spaced from 3 to 4 in apart on each side of the cut web, and test it for the given conditions. In the case for shear alone, assuming two rows of rivets, divide the maximum shear at the splice by the number of rivets to find the stress r_s per rivet due to shear. In case the bending moment is considered r_1, the value left for bending is $\sqrt{r^2 - r_s^2}$, where r is the value of one rivet, in this case probably in bearing on the web. Suppose in Fig. 15*a*, the outside rivet at distance y_1 from the neutral axis to be stressed to this moment, then the load on any rivet at distance of y from the neutral axis will be $y\ r_1/y_1$ and the moment of this about the neutral axis will be $y^2\ r_1/y_1$ and the moment of a row of these will be

$$2 \sum_0^{y_1} y^2 \frac{r_1}{y_1} = 2 \frac{r_1}{y_1} \sum_0^{y_1} y^2 \quad (a)$$

The bending moment which the web can bear as a beam is SI/c which, for rectangular shapes, reduces to $1/6\ Sth^2$ (*b*). Then the required number of rows will equal (*b*) divided by (*a*). If the result is say 2½ rows, respace the rivets and try again. Fig. 15*b* shows a second type of splice which is used. The top and bottom splice plates are figured with their rivets to carry the moment and the vertical plate in the center to carry the shear.

(*b*) (*a*)

Fig. 15

Rivet Values. In considering the conditions to which rivets are usually subjected in bridge work, they may be reduced to those of (1) single shear and (2) double shear or bearing. In the first case, the rivets are assumed to fail by shearing off on the one area between the two plates. In the second case, shear will occur on two areas and the rivet is twice as strong provided the plate does not crush. The value of the rivet in single shear is the area of the rivet multiplied by its shearing value per unit area as determined by the specifications. The bearing value of the rivet is the diameter of the rivet multiplied by the thickness of the plate multiplied by the bearing value per unit area. In any case, determine the action to which the rivet is subjected and take the lesser value. Tables giving these values for different size of rivets may be found in the steel handbooks, see (6) and (7).

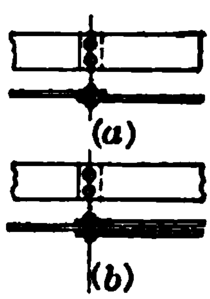

Fig. 16

Trusses are framed structures so proportioned and connected that they act together and carry the known loads to which they are subjected. In shape, a truss is usually made up of a combination of triangles. The different members are usually subjected to either tension or compression, and are connected together by either pins or rivets. A few members are designed to withstand both tension and compression, and occasionally a member is subjected to a live cross loading. The solving of a truss to find the stresses in the members is a problem, or a succession of problems in mechanics which generally depends upon the fundamental conditions for equilibrium for concurrent and non-concurrent forces. A truss is said to be STATICALLY DETERMINED with regard to the inner forces when it is possible, by the principle of statics, to obtain the stresses in all of its members. If n is the number of joints in a truss and m the number of bars, the condition that the structure shall be statically determined with regard to the inner forces is that $m = 2n - 3$. In determining the stresses, it is assumed that the parts are hinged together so that there is perfect freedom of motion without friction. This assumption is, however, never fulfilled and the rigidity of the joints causes a tendency for bending of the parts, and thus other forces, called secondary stresses, are brought into action. These latter forces are generally omitted from consideration even tho they may be of considerable magnitude. Two trusses connected together by means of the floor and lateral bracing form a bridge which may be either deck or thru. Fig. 17 shows a diagram of the different members. Sometimes trusses are used in which the top lateral bracing must necessarily be omitted on account of low head room. Figs. 18 and 19 show two such trusses in which will be noticed the method of side bracing which takes the place of the top lateral system. This type of bridge is apt to lack in lateral stiffness and should be used with care.

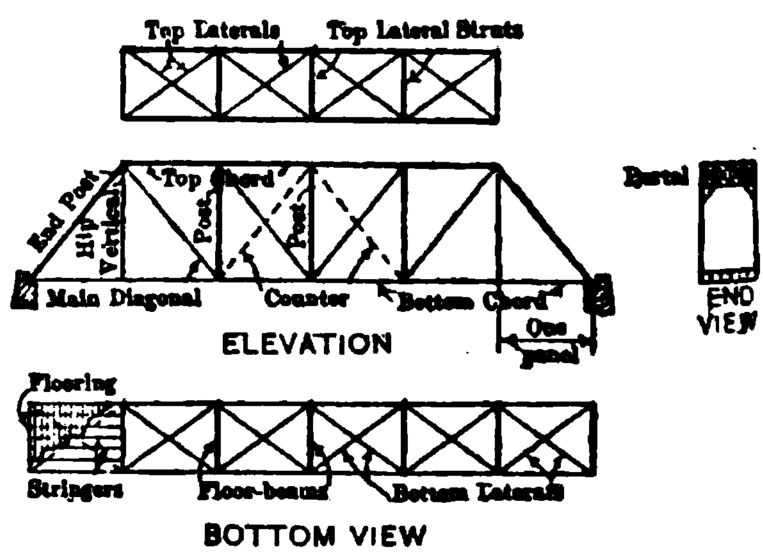

Fig. 17

PIN-CONNECTED trusses are used for highway bridges of about from 120 to 150 ft and over. RIVETED CONNECTIONS are used for spans of the shorter

lengths. In the pin-connected trusses, the tension members are usually eye-bars and all main connections of truss members are made by pins. If pins are not used, these connections are made by means of plates and rivets and the members are built sections, no eye-bars being used.

Types of Trusses. The most common types in use for steel highway bridges are the Pratt, Warren, Camel-Back, Baltimore, and Petit. Most of these are capable of modification. Fig. 20 illustrates the different types.

The Method of Computing Stresses is based upon the application of the three equations of equilibrium $\Sigma V = 0$, $\Sigma H = 0$, and $\Sigma M = 0$ upon

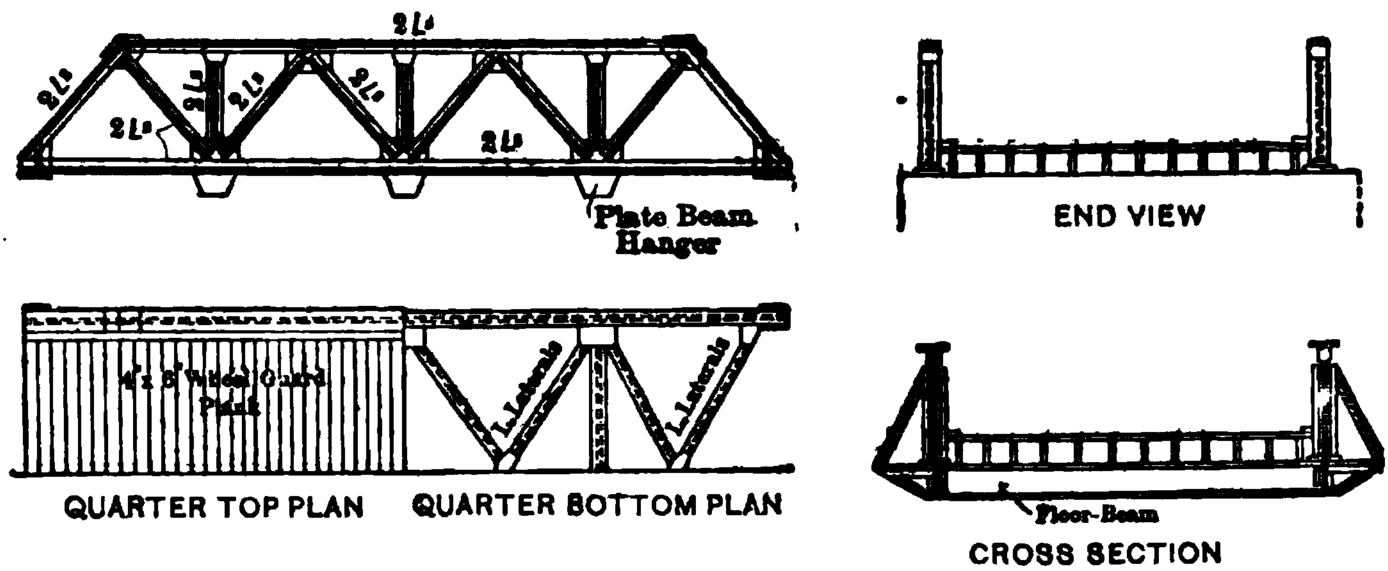

Fig. 18

a section of the truss. When the section is taken about a joint where all the members intersect, the last equation is eliminated. When the section is taken vertically or diagonally thru the truss, all three apply. In general, this application may be reduced to three methods: (1) METHOD OF SHEARS; (2) METHOD OF JOINTS; and (3) METHOD OF MOMENTS. It is usually possible to select the section in such a way that only one method need be applied in order to determine the stress in any one bar. In general, the method of procedure is as follows: (1) Take a section cutting not more than three unknown members. Never take the section thru a joint. (2)

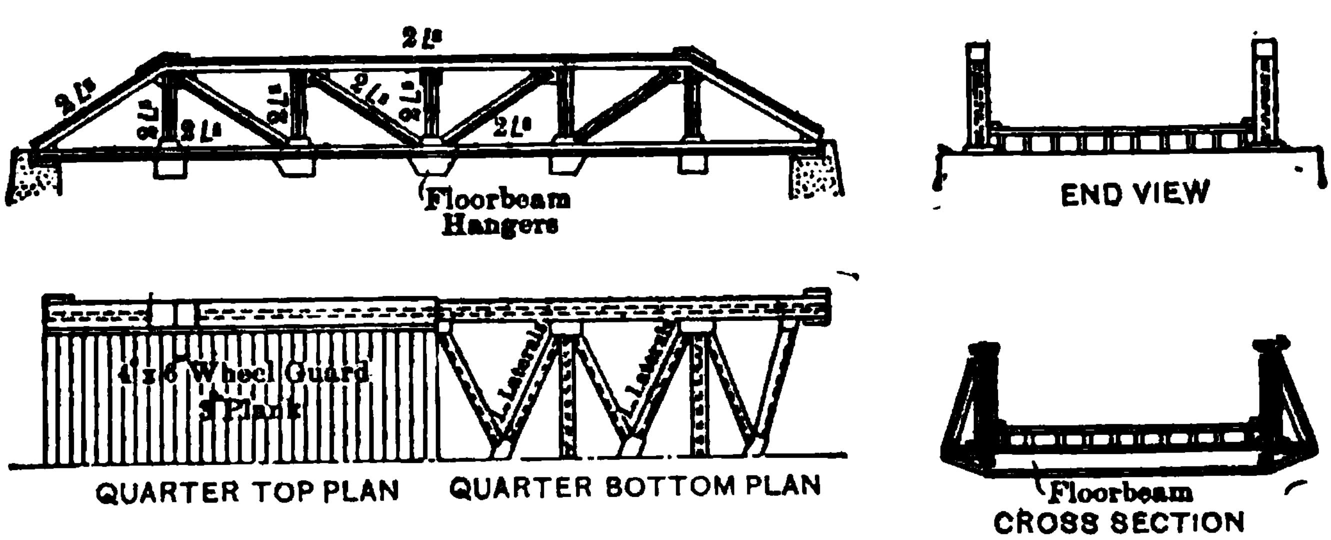

Fig. 19

Remove the truss on one side of the section. (3) Replace the cut members by forces. Place these forces outside of the section and assume compression to act toward the section and tension to act away from it. (4) Write

equations of equilibrium, and solve them for the unknown quantities. Usually the direction of the forces applied to the cut members will be known from the nature of the problem. If one direction is not known, it may

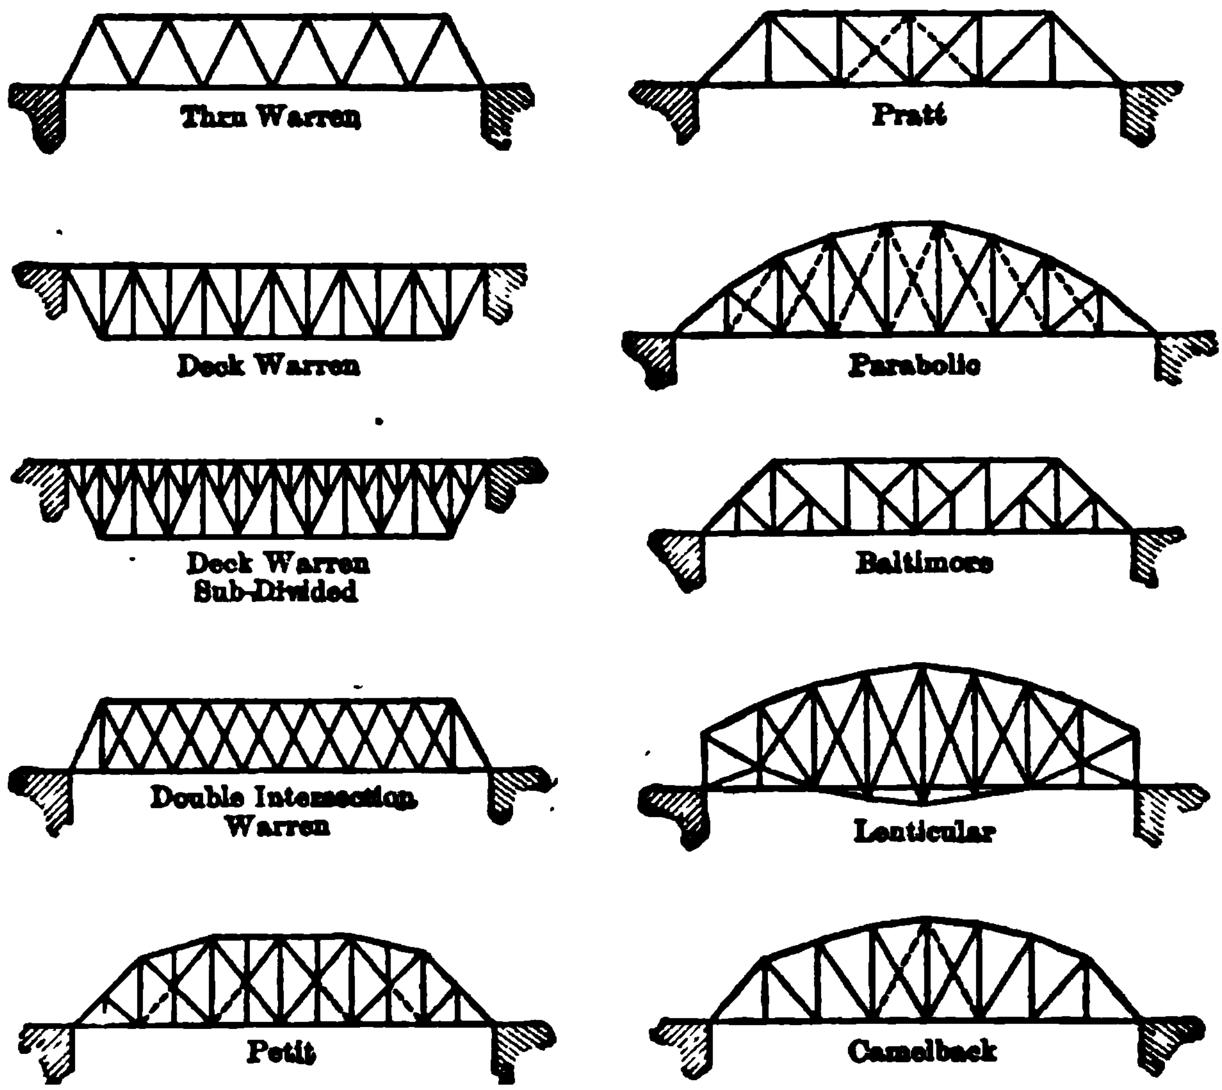

Fig. 20

be assumed, and if the resulting value as determined by solving the equation is negative, it should be reversed.

In Fig. 21*a*, suppose it is desired to obtain the stress in the diagonal member cut by section *m n*. Remove that part of the truss to the right of the section, and Fig. 21*b* results. It is known that under the loading the top chord is in compression and the bottom chord is in tension, hence place forces S_1 and S_2 as shown. Assume S to be in tension as shown. Writing $\Sigma V = 0$, $200 - 25 - 100 + S_{vc} = 0$, from which $S_{vc} = -75$, showing that S acts in the opposite direction or in compression. It should be noticed that instead of removing that portion of the truss to the right of the section, the left side could have been removed and the same result obtained.

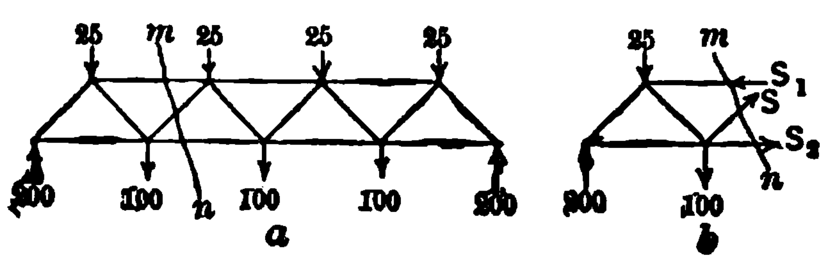

Fig. 21

Pratt Truss. As an example of the application of the foregoing principles, assume a truss as shown in Fig. 22. Width of roadway 17 ft, live load 1600 lb per ft of bridge, dead load 600 lb per ft. This will give panel loads of 16 000 and 6 000 lb for one truss. Assume ⅔ of the dead load applied to the bottom chord and ⅓ to the top chord.

Dead Load Stresses. Since the dead load is a fixed loading, the stresses caused by it may be conveniently found by a method of INDEX STRESSES, obtained by the METHOD OF JOINTS, as follows: Begin at joint U_2 and take a section around the joint as shown.

Remove the rest of the truss and place arrows on the forces cut, considering compression acting toward the joint (see Fig. 22*a*). Applying $\Sigma V = 0$, $-2 + s = 0$, or $S = 2$ in compression. Proceed to L_3, take section as before and apply $\Sigma V = 0$ (see *b*). $-2 - 4 + 2S = 0$. $S = 3$, in tension. Proceed to U_2 (see *c*). $-2 - 3 + S = 0$. $S = 5$, in compression. Proceed to L_2 (see *d*). $-5 - 4 + S = 0$. $S = 9$, in tension. Proceed to L_1 (see *e*). $-4 + S = 0$. $S = 4$, in tension. Proceed to U_1 (see *f*). $-2 - 9 - 4 + S = 0$. $S = 15$ in compression. Proceed to L_0 (see *g*). $R_L - 15 = 0$, $R = 15$. As $R_L = 2\frac{1}{2} \times 6 = 15$, these two results check. It should be noted that the values found are vertical components and, unless the member is vertical, these must be multiplied by L/h to obtain the

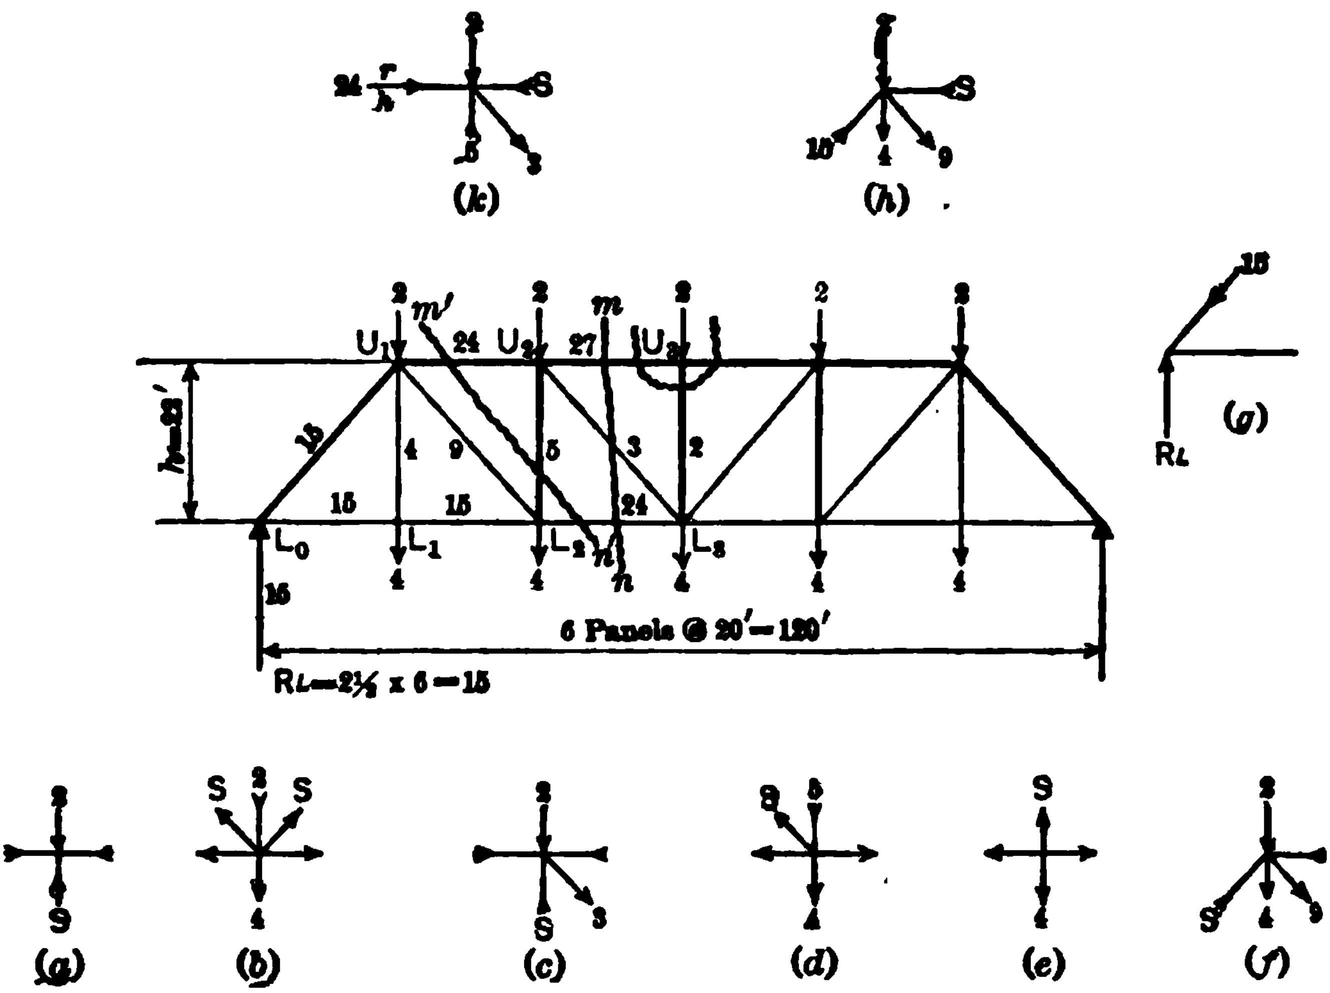

Fig. 22

stress, where L is the length of the member. Now, proceeding again to U_1, and taking a section around the joint, the forces are as in *h*. Apply $\Sigma H = 0$. $15\ p/h + 9\ p/h - S = 0$. $S = 24\ p/h$. Again, it must be remembered that both 15 and 9 are vertical components and to find the horizontal component of a force, having given its vertical component, multiply by the horizontal over the vertical in the triangle of forces, or if p is the panel length, multiply by p/h. Proceed to U_2 (see *k*). $24\ p/h + 3\ p/h - S = 0$. $S = 27\ p/h$. In this way, figures may be written on both top and bottom chords which, when multiplied by p/h, become the stresses in these chords. The top chord stress may also be obtained by the METHOD OF MOMENTS as follows: Take a vertical section such as *m n* cutting the top and bottom chords and the diagonal, and remove that part of the truss to the right, and apply $\Sigma M = 0$ at the intersection of the bottom chord and diagonal, the latter being also assumed as unknown. $15 \times 3p - 6 \times 2p - 6 \times p - Sh = 0$, from which $S = 27\ p/h$ as before. Any of the chords may be found in a similar manner. The diagonal stresses may also be obtained by the METHOD OF SHEARS as follows: Use the same section *m n* and remove that part of the truss to the right as before, apply $\Sigma V = 0$ to those forces on the left of the section. $15 - 2 \times 4 - 2 \times 2 - S = 0$, from which $S = 3$ as before. It will be noticed that the value of the shear on this section is 3, hence this method has been called the method of shears, and is applicable to any truss which has parallel chords.

Live Load Stresses. Usually take a section entirely thru the panel containing the member in question, and for chords load for maximum moment. For U_2U_3 take

section $m\ n$. Remove part of truss to right, and write moments of forces to left about L_3. The diagonal and bottom chord which are cut by this section, and are unknown, are eliminated because they pass thru L_3, the center of moments. As the chords may be considered to take the moment, a maximum moment is desired at L_3 which will occur with the entire bridge loaded. $R_L = 2\frac{1}{2} \times 16 = 40$. $40 \times 3p - 16 \times 2p - 16 \times p - Sh = 0$. $S = 65.5$. The maximum moment at the center is also $1/8 \times 16/20 \times \overline{120}^2 = 1440$. $1440/22 = 65.5$. As the web members take the shear, the live loading should be placed for a maximum shear on the section cutting the member considered. For U_2L_3 take section $m\ n$. Load from right to L_3. $R_L = (1 + 2 + 3)\ 16/6 = 16$. Apply $\Sigma V = 0$ using all forces to left of section, remembering that the top and bottom chord, altho cut, can not take a vertical component. $16 - S_{vc} = 0$ or $S = 16\ L/h$. For U_2L_2 take section $m'\ n'$, load for a maximum positive shear on this section, and the loading is the same as for U_2L_3. $R_L = 16$. $\Sigma V = 0$ gives $16 - S = 0$ or $S = 16$. U_1L_1 is a tension member and can only be stressed by a load on L_1. If the live floor beam reaction is larger than the panel load of 16, it should be taken in place of the latter for this member. To find whether a COUNTER, U_3L_2 is required, load for maximum negative shear on section $m\ n$. Place live load on L_1 and L_2. $R_L = (4 + 5)\ 16/6 = 24$. Shear $= 24 - 32 = -8$. This shows that for this loading U_2L_3 would be in compression, and as this compression is greater than the dead load tension, and as an eye-bar can take no compression, a member U_3L_2 is necessary. An investigation of the next panel to the left will show positive shear even when loaded for a negative, and no counter is needed.

Warren Truss. See Fig. 23. Assume a dead load of 700 lb per ft and a live load of 1600 lb per ft of bridge. This gives a live panel load of 16 000 lb for each truss. Assume the dead load to be distributed as shown.

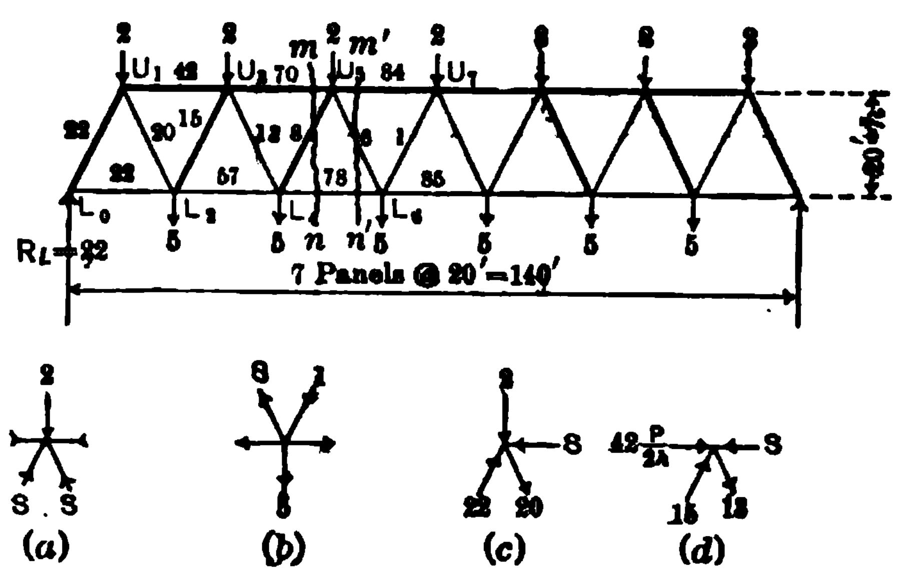

Fig. 23

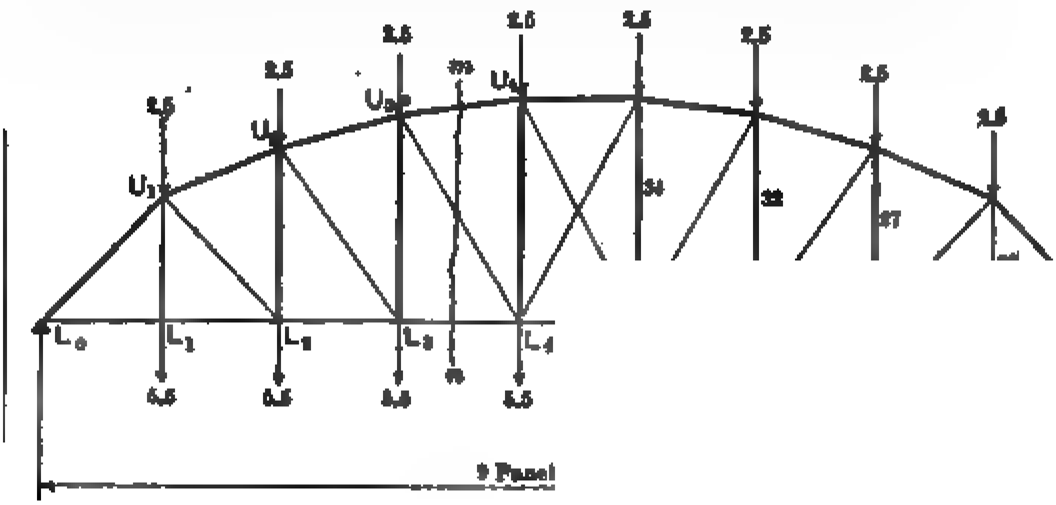
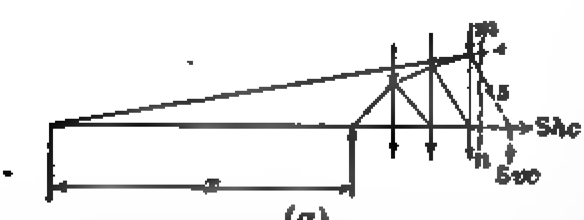
Dead Load Stresses may be found by writing index stresses. Take a section about U_7 (see a). Apply $\Sigma V = 0$. $-2 + 2S = 0$. $S = 1$. Proceed to L_6 (see b). $\Sigma V = 0$ gives $-1 - 5 - S = 0$. $S = 6$. Proceed in this way from joint to joint until R_L is reached. R_L also equals $3 \times 5 + 3\frac{1}{2} \times 2 = 22$, which checks the result already found. For the chords, take section at U_1 (see c). Apply $\Sigma H = 0$, remembering that the figures on the chords just found are vertical components. $22p/2h + 20p/2h - S = 0$. $S = 42\ p/2h$. Proceed to U_3 (see d). $42\ p/2h + 15\ p/2h + 13\ p/2h - S = 0$. $S = 70\ p/2h$. Note that the horizontal leg of triangle for reducing components is $p/2$. Check the last result by method of moments. Take section $m\ n$, and remove right part of truss. Take center of moments at L_4 and write moments of all forces to left of section. $22 \times 2p - 5 \times p - 2 \times 2p - Sh = 0$. $S = 35\ p/h = 70\ p/2h$. The bottom chords may be found in a similar manner, taking the center of moments above.

Live Load Stresses. As the loading for maximum moment at any section is a full one, the live load chord stresses may be determined in a manner similar to that explained for dead stresses. It should be noted that, if index stresses are written for live loading, the values written on the web members are of use only in determining the chord stresses, as web stresses have maximum values for partial loadings. To find the maximum stress in U_5L_6 take section $m'\ n'$ and load for a maximum positive shear on this section, or from the right up to L_6. $R_L = 10/7 \times 16 = 22.9$. Apply $\Sigma V = 0$ and the stress in member is $22.9\ L/h$ tension. The maximum stress in other web members may be found in a similar manner, always taking a section cutting the bar in question. Thus for U_5L_4 the section would be $m\ n$ and the loading the same as for U_5L_6, and the stress will be the same as before but will be compression. As no

counters are used in a truss of this kind, the web members must be investigated for a reversal of stress and if such is found they must be proportioned accordingly. Thus U_5L_4 is in tension under a full load or under positive shear. Load for negative shear on section $m\ n$. Load from left up to L_4. $R_L = (11/7)\ 16 = 25.1$. Shear on section is $25.1 - 32 = -6.9$. As the dead load tension is 6, this means that a reversal of 0.9 occurs. See Art. 4. The maximum negative live shear on $m'\ n'$ will also be 6.9 and, as the dead shear is 8 positive, no reversal can occur in this member or in any of the web members to the left. A reversal will occur in U_7L_4, and will be found by loading from the left up to L_4. Proceed as before.

Camel-Back Truss. See Fig. 24. This truss is also called the Parker Truss, and may be used for spans from about 175 ft to about 250 ft in length. The top chord approaches a parabola in form, the length of the hip vertical being made long enough to provide sufficient head room, and





(a)
Fig. 24

at the same time give a portal deep enough to provide sufficient stiffness. Assume a dead load of 800 lb per ft of truss and a live load of 1550 lb per ft of truss. This gives a live panel load of 15 500 lb per truss. Assume dead load distributed as shown.

Stresses. Altho the method of index stresses may be used for dead loads, it must be modified as the chords are not parallel. This method will be omitted here. The dead and live stresses may both be conveniently found by the method of moments. In general the chords will be a maximum for a full live loading and the web members will be a maximum for the live loading which gives a maximum shear on the section cutting the member. To find dead stress in $U_3\ U_4$, take section $m\ n$. Write moments about L_4. $R_L = 4 \times 8 = 32$ dead. $32 \times 4p - 8 \times 6p - S_{hc} \times 34 = 0$. S_{hc} = horizontal component $= 47.1\ S = 47.1\ L/p$ where L = length of member. The live stress may be determined by multiplying this value by the ratio of the live load to the dead load, or 15.5/8. The stress in this member could also be determined by taking the same section and applying $\Sigma V = 0$, after first finding the vertical component in $U_3\ L_4$ for this loading, which is not the loading for a maximum in this diagonal. This would obtain the vertical component of $U_3\ L_4$ instead of the horizontal. This result multiplied by $L/2$ should equal that found by the other method. To find the maximum stress in $U_3\ L_4$ take same section and load with live load up to L_4. $R_L = 32$ dead and 25.8 live. Find where $U_3\ U_4$ intersects the bottom chord and take this point as the center of moments, considering the diagonal $U_3\ L_4$ to be resolved into its horizontal and vertical components at L_4. Let X = distance from this intersection to L_0. $X +$

$4p : 84 :: X + 3p : 32$ from which $X = 13p$ (see *a*). Take moments about this point. $-32 \times 13p + 8\ (14p + 15p + 16p) + S_{vc} \times 17p = 0$ from which $S_{vc} = 3.3$ dead. $-25.8 \times 13p + S_{vc} \times 17p = 0$ from which $S_{vc} = 19.7$ live. To find the stress multiply these values by L/h. This must have counters in panels where, by loading for negative shear, the stresses in the main diagonals are reversed. The maximum stresses in diagonals, verticals, and counters may be found as explained for $U_3 L_4$, being careful to load correctly and use the proper center of moments. In the center panel, the chords are parallel, which simplifies the calculations for stresses in these members.

Baltimore Truss. See Fig. 25. This truss is of the Pratt type with a secondary system of webbing. This allows economy in the length of

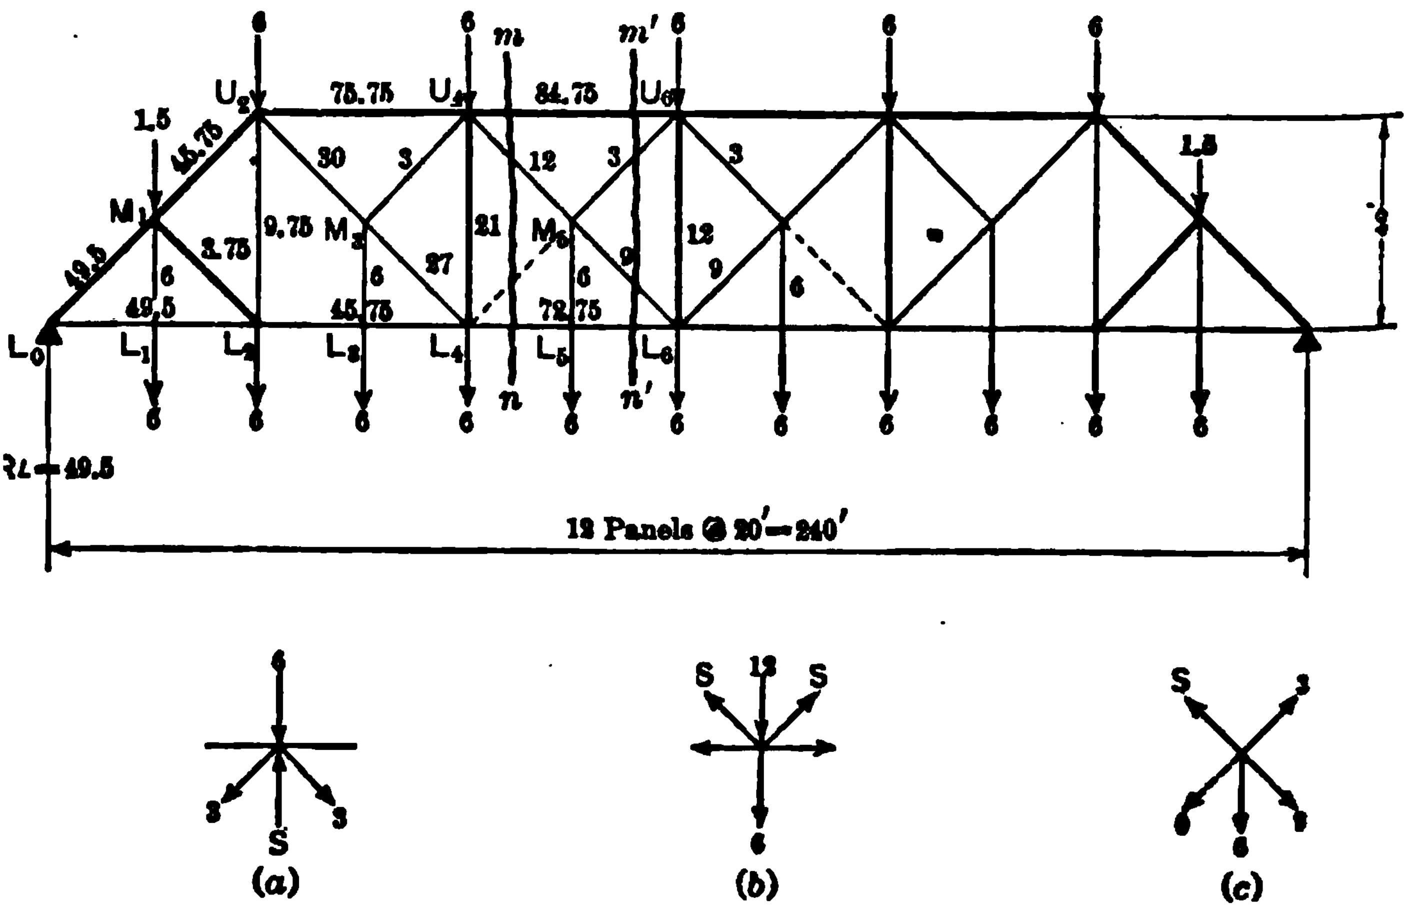


Fig. 25

panels and slope of diagonals. It may be used for spans of about the same length as for the Camel-Back truss, altho the Petit type would probably be selected in preference for spans approaching the upper limit. This is not always the case, however, as Baltimore trusses of over 300 ft in length are found. The secondary system may be arranged as in Fig. 26, and in some cases the short verticals are extended to meet the top chords and aid in supporting the dead

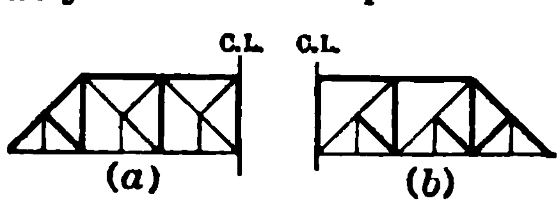

Fig. 26

load of these heavy members. Counters are required in those panels where the main diagonal may be reversed in stress by the live load. Neglecting the action of the counter $L_4 M_5$, the only way in which a bar like $M_5 U_6$ can be stressed is by the loading on L_5 in which case the stress is one-half the load. To see what effect a load on L_5 has on $M_5 L_6$, draw an influence line for vertical component of this bar (see Fig. 27). As the load of unity passes from R_R to

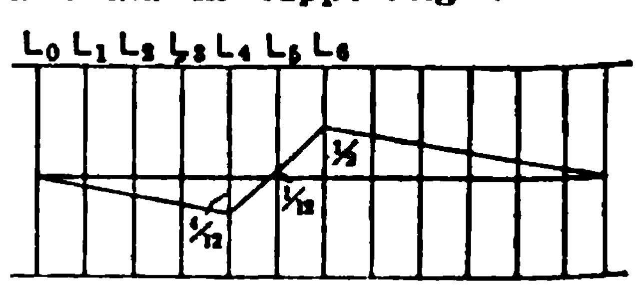

Fig. 27

L_6, the vertical component in $M_5\,L_6$ is the shear in the panel. For these loadings, $M_5\,U_6$ is not in action, and for the load at L_6 equals 1/2. When the load is on L_5 the stress in $M_5\,U_6$ is 1/2, and $R_L = 7/12$. Applying $\Sigma V = 0$ on a section thru the panel, $7/12 + 1/2 - 12/12 - S_{vc} = 0$ $S = 1/12$. With a load on L_4 the counter is in action and the stress in $M_5\,L_6$ is zero. If no counter was present the stress would show a reversal of 4/12. From an inspection of this influence line, it is plainly seen that to obtain a maximum stress in $M_5\,L_6$, the live load should be placed up to and including L_5 from the right. If the loads differed in weight, the heaviest loads should be placed as near to L_6 as possible. As a concentrated system of unequal moving loads is seldom used for highway bridge analysis, the method of determining such loading by a further use of the influence line is omitted.

Dead Load Stresses. Assume a dead load of 900 lb per ft of bridge and a live load of 1500 lb per ft of bridge. Assume the dead load distributed as shown and write index stresses. First write stresses on short verticals and short diagonals, and then take section around U_6 (see Fig. 25*a*). Apply $\Sigma V = 0$. $-6 - 3 - 3 + s = 0$. $S = 12$. Proceed to L_6 (see *b*). $-12 - 6 + 2s = 0$. $S = 9$. Proceed to M_5 (see *c*). $\Sigma V = 0$ gives $3 - 9 - 6 + s = 0$. $S = 12$. Proceed in similar manner from joint to joint as in previous trusses. Notice, in obtaining chord stresses, that $2p/h = 1$.

Live Load Stresses. Take $U_4\,U_6$. Section $m\,n$ cuts three bars only as the counter is not in action under a full load. $R_L = 5\tfrac{1}{2} \times 15 = 82.5$. Write moments about L_6, $82.5 \times 6p - 15 \times 14p - Sh = 0$. $S = 142.5$. For bar $M_5\,U_6$ take section $m'\,n'$. From a study of the influence line given in Fig. 27, it was decided to load up to L_5. $R_L = 35$. Apply $\Sigma V = 0$ on section, remembering that stress in $M_5U_6 = 7.5$. $35 - 15 + 7.5 - S_{vc} = 0$. $S_{vc} = 27.5$. For vertical $U_4\,L_4$ take a diagonal section cutting $U_2\,U_4$, the vertical, and $L_4\,L_5$. The worst possible condition for this member will occur when the bridge is loaded from the right up to L_3, omitting the load on L_4. This may be seen from Fig. 28, which is the influence line for stress in $U_4\,L_4$, considering counter $L_4\,M_5$ out of action. With this loading apply $\Sigma\,V = 0$ on the section.

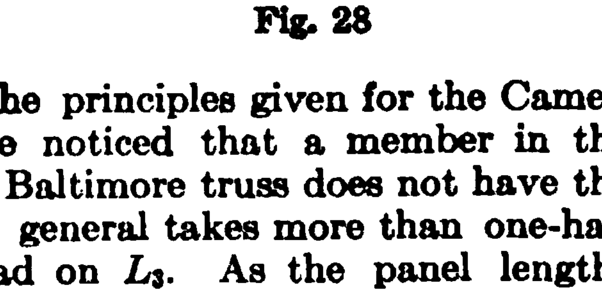

Fig. 28

Petit Truss. This truss, also called the Pennsylvania Truss, is of the Baltimore type with an inclined top chord. This truss is used for long spans. The analysis consists of the application of the principles given for the Camel-Back and Baltimore trusses. It will be noticed that a member in the Petit truss corresponding to M_3U_4 in the Baltimore truss does not have the same slope as the main diagonal and in general takes more than one-half of the load on L_3. As the panel lengths are usually equal, the vertical components of the stresses in these two diagonals may be found as follows. See Fig. 29*a*. Let $A\,C$ = load on L_3 drawn to any convenient scale. Draw $A\,B$ parallel to $U_2\,M_3$ and $C\,B$ parallel to $M_3\,U_4$, locating point B. Then $D\,B$ is vertical component of the main diagonal and $B\,E$ is vertical component of the short diagonal. This principle may be performed very quickly analytically. From the dimensions given in Fig. 29*b*:

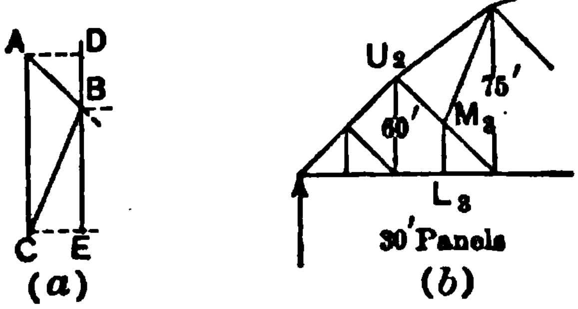

Fig. 29

$$D\,B = 30/75 \text{ of } A\,C, \text{ and } B\,E = 45/75 \text{ of } A\,C.$$

Parabolic Trusses have been used to a considerable extent in certain parts of the country for highway bridges. The two most common types

are the Sickle and the Lenticular types. The former may be either deck or thru and has the loaded chord straight and the panel points of the unloaded chord located upon the arc of a parabola. The Lenticular truss is of the thru or half thru type, and has the panel points of both chords located on the arcs of parabolas. The same principles of analysis already described apply to these trusses. The following peculiarities should be kept in mind. For a full uniform loading, the horizontal component of chord stress is constant. For this condition there will then be no stress in any of the diagonals. With equal live panel loads, placing them to obtain a maximum in the different diagonals, the horizontal component of maximum diagonal stress is constant. It is necessary to have counters in each panel. For thru bridges, the verticals will be subjected to tension under a full loading, and compression under a partial loading. By applying these principles, the truss is very simple of analysis.

Methods of Design. Tension Members are usually designed by the formula $A = P/S$, where A = net area required, P = maximum stress, S = allowable unit value of material in tension. In built-up members take account of area lost in any section by rivet holes, so that gross area will make up the loss and required net area will be obtained. In riveted trusses, tension members are usually made of angles, or channels, or a combination of plates and angles, or plates and channels. In pin-connected trusses, eye-bars are used except for members subject to a reversal of stress. It is common to make the first two panels of bottom chord of built sections for this reason. In case it is desired to obtain the stress in the bottom fiber of an eye-bar due to its own weight, to see that S is not exceeded, after having obtained size by above method, use following formula where h = breadth of bar in in:

$$S_w = \frac{4\ 900\ 000\ h}{\dfrac{P}{A} + 23\ 000\ 000\left(\dfrac{h}{L}\right)^2}$$

Compression Members are made of built sections, the most common examples being as shown in Fig. 30. Note that the dotted lines represent lattice bars. For top chords and end posts, c and f are the most common, altho a and d are sometimes used. For intermediate posts, a, b, d, and e are common. For the hip vertical, g and h are examples.

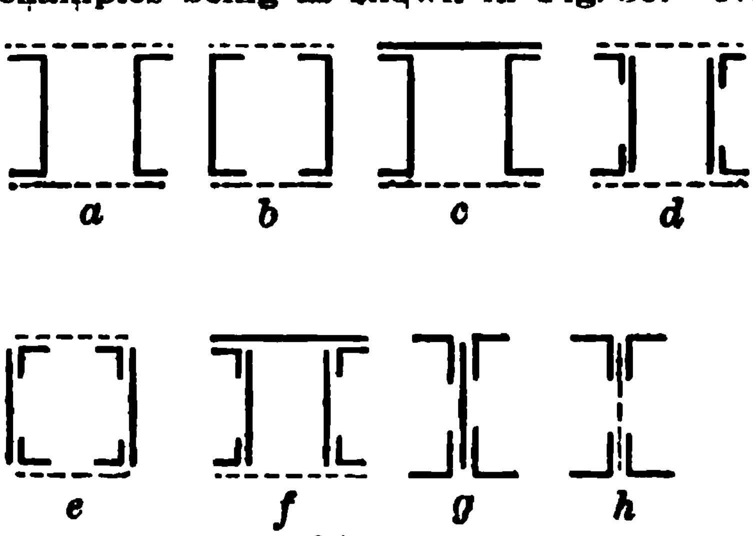

Fig. 30

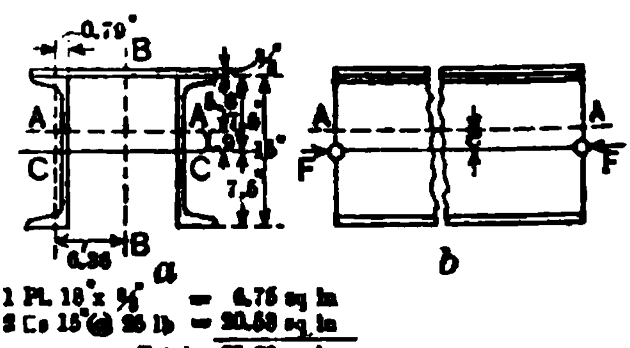

Fig. 31

Design of a Top Chord Section. Let it be required to design a top chord section whose length is 254 in for a live stress of 181 700 lb and a dead stress of 156 000 lb. For unit stresses see Specifications. Add the live and half of the dead, and use live load formula $S = 12\ 000 - 55\ L/r$.

Assume two 15 in channels and a ⅜-in cover plate. The least radius of gyration r may be assumed as 4/10 of the depth for a trial area, or 6.1. Then $S = 9710$ and $A = 259\ 700/9710 = 26.7$ sq in. Make up section as shown in Fig. 31. Find true least

radius of gyration, by obtaining moments of inertia about axes AA and BB, when $r^2 = I/A$. First locate axis AA, which is the gravity axis of the section. Take moments about lower edge of section and divide by sum of areas. $6.75 \times 15.19 + 20.58 \times 7.5 = 256.88$. $256.88/27.33 = 9.4$. $9.4 - 7.5 = 1.9$. For tabulated moments of inertia of shapes, see steel hand-books. $I_{AA} = 640 + 20.58 \times \overline{1.9}^2 + 6.75 \times \overline{5.79}^2 = 940.55$. $r^2 = 940.55/27.33 = 34.41$. $r = 5.86$. $I_{BB} = 16.96 + 20.58 \times 6.36^2 + 1/12 \times 3/8 \times \overline{18}^3 = 1032$. $r^2 = 37.76$. $r = 6.1$. Allowable unit stress $= S = 12\,000 - 55 \times 254/5.86 = 9616$. Actual unit stress $= 259\,700/27.33 = 9502$ and the area is sufficient for direct stress. The wind stress was not considered as it was less than 30% of that allowed for live and dead.

THE WEIGHT OF THE MEMBER tends to cause compression in the top fibers and tension in the bottom. The location of the pins determines the points of application of the axial forces (see Fig. 31*b*). If these points are below the center of gravity axis, there is a tendency for tension in the top fibers and compression in the bottom. It is therefore possible to place the pins at a distance e below the center of gravity axis so that these two tendencies will neutralize each other. $M = \frac{1}{8} w L^2$, where w = weight per foot. M due to eccentricity $= Fe$. If these two moments are placed equal, $e = w L^2/8F$. Conditions, such as necessary clearness for eye-bar heads, will not always allow this location, in which case the stresses caused by these two factors may be found by the following formula:

$$S_1 = \frac{Mc}{I - \frac{PL^2}{KE}}$$

S_1 = fiber stress due to cross bending. M = bending moment in inch-pounds c = distance from neutral axis to most extreme fiber on side under consideration. I = moment of inertia of section about neutral axis. P = total direct stress in member. L = length of member in inches. E = modulus of elasticity of material and K = a constant usually taken as 10 for a member having hinged ends, 24 for one end fixed and the other hinged, and 42 for both ends fixed. If P is tension, change negative sign in denominator to positive.

Design of End Post. In addition to direct stress due to live, dead and wind loads, and flexure due to weight and eccentricity, the end post is subjected to a flexure caused by a bending moment due to action of the wind on the portal bracing, which may amount to considerable. It is, however, seldom that wind stresses and live load stresses are a maximum together, and this is especially true in highway bridges. For this reason, direct wind stresses are neglected in main truss members unless they exceed a given percentage of the dead and live in the member considered, or unless they produce reversals or a bending. See Art. 4, SPECIFICATIONS. When direct or flexural wind stresses are considered, the allowable unit stress is increased by this percentage. Some specifications give this increase as 25%; Cooper gives 30%, and Ketchum allows 50% for both direct and flexural wind stresses. Some designers in computing flexure in the end post of long spans assume only half the live load with the wind load. Unless the end floor beam is rigidly connected to the end post, it is customary to consider the latter hinged at both ends, altho the following rule may be used when this condition does not exist. Multiply wind reaction at top of end post by half distance from L_0 to portal bracket and, if this is less than half the dead stress in post multiplied by distance c to c of bearings on pin, call post fixed at bottom, and take point of contra flexure half way from L_0 to portal bracket.

In order to show effect of wind on flexure, let it be required to examine the section shown in Fig. 32. Live stress including impact 185 600, dead stress 133 500. L = 256

in. Post assumed as fixed at base. Locate neutral axis. $20.58 \times 7.5 + 9 \times 15.25 = 291.6$. $291.6/29.58 = 9.9$. $I_{AA} = 319.9 \times 2 + 20.58 \times \overline{2.4}^2 + 9 \times \overline{5.35}^2 = 1016$. $r = \sqrt{1016/29.58} = 5.86$. $I_{BB} = 2 \times 8.48 + 2 \times 10.29 \times \overline{6.36}^2 + 1/12 \times \frac{1}{2} \times \overline{18}^3 = 1092$. $r = 6.08$. Assume point of contra flexure as in Fig. 32b. Direct compression due to lateral forces $= 16\,000 \times 19.17/21.5 = 14\,270$. Total direct compression $= 333\,400$. M at foot of knee brace $= 8\,000 \times 10.5 \times 12 = 1\,008\,000$ in lb. Use formula $S = 16\,000 - 70\ L/r$. $S = 16\,000 - 70\ 356/5.86 = 11\,750$. Area required for live and dead loads = 27.16 sq in. For stress due to wind moment:

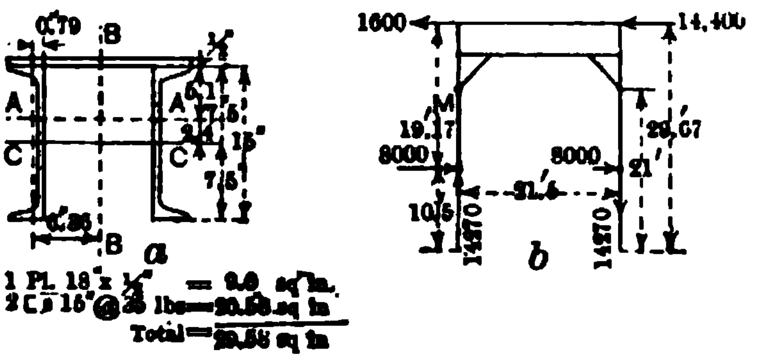

Fig. 32

$$S_1 = \frac{1\,008\,000 \times 9}{1092 - \dfrac{333\,400 \times \overline{230}^2}{24 \times 30\,000\,000}} = 8502$$

Actual fiber stress $= 8502 + \dfrac{333\,400}{29.58} = 19\,783$. Allowable unit stress $= 1.50 \times 11\,750 = 17\,625$. Efficiency = 89%. Redesign for an efficiency of 100%. The stresses due to weight and eccentricity, if desired, may be found as before indicated and combined with the above values.

Design of Intermediate Posts. The intermediate posts are designed in a manner similar to that already explained for top chord and end post. In investigating flexural stress due to sway frame brace, assume half top panel wind load as transferred into bottom lateral system thru the post.

Stringers and Floor Beams should be designed as plate girders, or if I-beams are used, they are selected as in Art. 6.

Pins are figured as a beam and should be designed for bending, shear, and bearing. Having determined the packing of the members on the pin, the horizontal and vertical components of the stresses of these members are found. Note that a maximum stress will not occur in all members at the same time and that in general two or more cases must be considered, such as (1) maximum in diagonal, (2) maximum in chord. Compute moment at center of bearing of each member on pin for both horizontal and vertical component and take the resultant for the combination which gives a maximum. Do this for each case and take largest resultant. Tables in steel handbooks will give size of pin for different allowable fiber stresses. Obtain maximum shear and determine if the pin selected is of sufficient size to withstand shear and allow a safe bearing as required in specifications. Usually built-up members, such as posts, need reinforcing plates riveted on to satisfy the conditions for bearing. Before figuring moments, it is well to determine if these plates are required by assuming the size of pin. After pins are computed, it is usual to limit them to two sizes, altho sometimes three are used.

Camber. The deflection of a beam or truss under its own weight and the loads which come upon it is caused by the elastic properties of the material and by imperfect workmanship. In short spans, the deflection is not important, but in spans of average or considerable lengths it should be taken into consideration. This is especially true in pin-connected bridges, where there must be more or less play in the joints. It is usual, in all except short spans, to provide a camber by making the top chord slightly longer than the bottom chord, in order that the truss shall assume

its theoretical form when fully loaded. The most common method in highway bridges is to make the lengths of the top chord panels longer than the bottom chord panels by 3/16 in for every 10 ft. This method, while empirical, gives good results in most cases. If it is necessary to use more refined methods, as might be the case for extra long spans, cantilevers, and draw spans, the deformations may be figured, and the tension members decreased and the compression members increased in length accordingly. For the more exact methods, consult references.

7. Timber Highway Bridges

Wooden Beams are designed by the formula $M = SI/C$, where M is the maximum bending moment, I, the moment of inertia of the section about the neutral axis, and C, the distance from the neutral axis to the most strained fiber. For the usual case, a wooden beam is of rectangular shape and of constant cross-section. For this condition, $I = 1/12\ b\,h^3$ and $C = h/2$. The above formula reduces then to $M = Sbh^2/6$. Beams which are unusually short and deep should then be investigated to see that the safe longitudinal shearing strength is not exceeded. If s is longitudinal shear per sq in, V is external shear, and A area of cross-section, then $s = 3\ V/2\ A$. It is usually only necessary to obtain the bending moment M, and select the safe working value S for the timber used, and figure $b\,h^2$, from which the dimensions may be selected to conform to commercial sizes. For working unit stresses see Sect. 2, Art. 5.

Wooden Columns are designed by the use of a column formula. See table in Sect. 2, Art. 5.

Trussed Beams are used when the span length becomes too great for an efficient use of simple beams. This limit is about 20 ft. There are two types, the King Post and the Queen Post (see Figs. 33 and 34). The King Post is used for spans from about 20 ft to about 25 ft, and the Queen Post for spans over 25 ft. Each may be used as a deck bridge, instead of thru as shown. In case of the deck structure, it should be noted that the inclined members become tension pieces and the vertical members compression pieces, and that the beams become the top instead of the bottom chord. The beam is usually one timber, or two or more timbers bolted together, extending over the entire span, and is therefore subject to continuous beam action. In designing such a structure, it is common to find the stresses on the assumption that the members together act as a truss, and add to the unit stress in the beam due to this action, the bending unit fiber stress due to direct loads. In the thru structure, the top chord, including the inclined members, are timbers, and the verticals are rods. In the deck structure, the bottom chord is usually one or more rods and the verticals become timbers. Care should be taken to make suitable joints at the intersection of timbers and to use washers and plates, or cast-iron caps, of sizes sufficient to transmit stress without producing too great unit pressure on the wood. If the floor of the bridge is supported directly upon the chords, as would be the case in a deck structure, the load becomes uniformly distributed and the beam is subjected to a cross bending in addition to the stress due to truss action. If the floor rests upon joists, which in turn are supported by beams at points a, the load becomes concentrated and the only cross bending is due to the dead weight of the beam which under usual conditions may be neglected. The following formulas are sufficient for practical purposes.

King Post (see Fig. 33), UNIFORM LOAD. Let w = load per ft, + = tension, and − = compression. $ab = +5.8\,w\,L$, $cb = -w\,L\,m/2\,h$, $ac = +w\,L^2/8\,h$. Unit stress in $ac = +w\,L^2/8\,b\,d\,h$, and to find total unit stress add to this the greatest fiber stress due to cross bending obtained by the formula $S_1 = +2.25\,w\,L^2/b\,d^2$. CONCENTRATED LOAD of W at a: $ab = +W$; $cb = -W\,m/2\,h$; $ac = +W\,L/4\,h$.

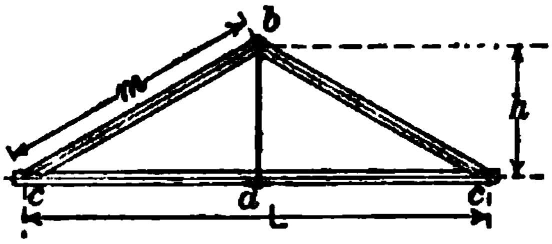

Fig. 33

Queen Post (see Fig. 34), UNIFORM LOAD. $ab = +11/30\,w\,L$; $cb = -w\,L\,m/3\,h$; $cc = +w\,L^2/9\,h$, $bb = -w\,L^2/9\,h$. Unit stress in $cc = w\,L^2/9\,b\,d\,h$, and to find total unit stress add to this $S_1 = +w\,L^2/b\,d^2$. CONCENTRATED LOAD of $W/2$ at points $a\,a$: $ab = +W/2$; $cb = -W\,m/2\,h$; $cc = +W\,L/6\,h$; $bb = -W\,L/6\,h$.

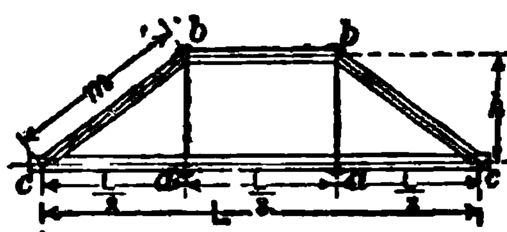

Fig. 34

Timber Bridges of the Howe Type (see Fig 35), altho formerly very common in certain sections, are not now built except in special cases, such as for temporary traffic, falsework, etc. These bridges are usually covered by a roof and sides to prolong their life. Many are in existence in New England rural sections, but they are gradually being replaced by steel bridges or concrete arches. The chords and diagonals are made of timbers and the verticals of rods. The stresses may be figured in the same manner as for the Pratt truss, which see. Usually counters of timber are placed in each panel, the same as shown in the figure for the two center panels.

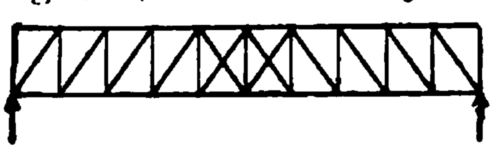

Fig. 35

8. Highway Bridge Floors

Width of Roadway. See also Art. 4, CLEARANCES. The width of roadway for a highway bridge is much more variable than for a railroad bridge. In general there is little variation in the clear width of the latter, the chief factor being the number of railroad tracks to be accommodated. The width of a highway bridge depends upon the volume of traffic, which in turn regulates the kind of wearing surface; the latter regulating the floor, or supports for the wearing surface. Thus a country bridge designed for loads under Art. 4, COOPER CLASS D, would probably have a floor of simple construction, such as plank, resting directly upon stringers, with a clear width of not less than 12½ ft, while if CLASS C were used, the width would be at least 14 ft. If it is desired to have vehicles pass each other on the bridge, these figures must be increased. Good practice inclines toward bridges of greater widths than these figures. The length of span must also be taken into consideration. Ketchum and the Mass. R. R. Comm. require the width between *c* to *c* trusses to be at least 1/20 span length, and the former, preferably, at least 1/12 span length.

CITY BRIDGES which carry almost constant traffic, must have a wearing surface of more durable material than plank. This requires a different arrangement of the floor system, and a width sufficient to take care of the traffic in both directions. This does not mean that it is necessary to have the same width as the city streets for traffic over a bridge is continuous, there being no necessity for stopping at the curb. There should be no difficulty in selecting a width of roadway in the case of country bridges, with or

without electric cars. For the case of suburban or city bridges, the case may call for study. The following data by Spofford (68b) will be of interest.

Horse-Drawn Vehicles. The width of ordinary horse-drawn vehicles as measured in the streets of Boston is given in the following table, in which (1) represents distance, in feet, out to out of hubs; (2) the distance, in feet, out to out of wheels; (3) the distance, in feet, out to out of whiffletrees:

	(1)	(2)	(3)
Hay wagon	7.75	7.00	8.00
Heavy express	7.65	6.70	7.90
Heavy express	7.80	6.70	7.60
Ice wagon	7.40	6.60	7.00
Hack	6.08	5.25	6.83
Coal wagon, 3-horse	8.50	....	10.83

Electric Cars. In comment upon the widths of electric cars, it may be noted that the Mass. Public Service Comm. specifies that the distance center to center of tracks, should be 9.71 ft, and that for this spacing a total width in the clear of 18.5 ft is required by two lines of the widest cars, 8.79 ft in width, used in Boston.

Width of Various Bridges with Traffic Statistics. Brooklyn Bridge. Width of roadway, two roadways 16 ft 9 in each between curbs, with single street-car track on each. Traffic in 1912, surface cars, round trip, 1 474 610; average per day, including Sundays, 4029 single trips; other vehicles, exclusive of trains, 1 282 000; average per day of 24 hr, including Sundays, 3503 single trips.

Manhattan Bridge. One roadway 35 ft between curbs, without street-car tracks in roadway. Total roadway vehicle traffic in 1912, 1 607 800; average per day, including Sundays, 4381 single trips.

Congress Street Bridge, Boston. One roadway 44 ft between curbs on fixed spans; 31 ft 4 in between curbs on draw-span. This bridge, including draw-span, is used regularly by three lines of vehicles, and can be used by four lines. No street cars. Traffic on Sept. 11, 1908, 7362 vehicles.

Rush Street Bridge, Chicago. Two roadways 17 ft 4 in between curbs. Two lines of traffic on each roadway. Traffic on Feb. 4, 1915, between 7 A.M. and 7 P.M. consisted of 11 594 horse-drawn and motor vehicles.

The following figures are from the 1911 Report of the London Traffic Branch of the Board of Trade and refers to traffic on 1 day in 1911, between 8 A.M. and 8 P.M.:

Waterloo Bridge. Width of roadway in the clear, 27 ft 6 in; 10 192 horse and motor vehicles; no street-cars.

Westminster Bridge. Width of roadway in the clear 54 ft; 14 618 horse and motor vehicles, including 2975 electric tram cars.

Blackfriars Bridge. Width of roadway in the clear, 73 ft 6 in; 14 067 horse and motor vehicles, including 1829 electric tram cars.

London Bridge. Width of roadway in the clear, 37 ft; 13 771 horse and motor vehicles; no street-cars.

Weighted Traffic Units. In order to accurately measure the capacity of a bridge or street in relation to traffic, it is evidently necessary to consider the character of the vehicles and their speed, as well as their number. For the purposes of making such a comparison, the London Board of Trade sets up as a unit a motor-cab or carriage, and assigns the following numbers to other classes of vehicles:

Trade Vehicles		Passenger Vehicles	
1 Horse, fast	8	Electric trams	10
1 Horse, slow	7	Omnibuses, horse	5
2 Horse, fast	4	Omnibuses, motor	3
2 Horse, slow	10	Cabs, horse	2
Motor, fast	2	Cabs, motor	1
Motor, slow	5	Carriages, horse	2
		Carriages, motor	1
		Barrows	6
		Cycles	½

The Board lays down the following definitions.

TRAFFIC VOLUME at a point is the average aggregate number of traffic units attributable to vehicles which pass it per min during the 12 hr from 8 A.M. to 8 P.M.

AVERAGE TRAFFIC DENSITY is the aggregate number of traffic units attributable to vehicles, which pass the point during the 12 hr, per min, per 10 ft of available carriageway.

GREATEST TRAFFIC DENSITY is the average density per min, per 10 ft of available carriageway, during the busiest hour, expressed in traffic units.

With the above units and definitions in mind, the following comparison of traffic on London bridges is clear:

	Westminster Bridge	Waterloo Bridge	Southwark Bridge	Blackfriars Bridge	London Bridge
Traffic volume	90.4	60.5	105.9	16.6	89.2
Average traffic density	20.8	22.0	14.4	5.8	24.1
Hour of greatest density	6 to 7	5 to 6	6 to 7	....	11 to 12
Density of that hour	23.8	22.5	15.3	....	27.4
Average vehicles	4.2	3.9	5.0	4.1	4.0

Wearing Surfaces and Their Supports. See Art. 4, FLOORS. The surfaces most commonly used are plank, wood block, stone block, and brick. Sheet-asphalt, bituminous pavements, and cement-concrete are also used under special conditions. Drowne (41) in a report to the 3rd Int. Road Cong., 1913, concluded that " If the support furnished the surface is unyielding. the wear of bridge surfaces of wood block, sheet-asphalt, stone block, brick and other similar types is not any different than it is under the same conditions on the street."

PLANK is used mostly for country bridges and may be of one thickness or two. The life of a plank floor is very variable, depending chiefly upon the amount and kind of traffic, and also upon the wetness of the seasons. This variation will be from a few months, if used near a city, to several years if in a place where travel is very light. Spruce is the most common plank altho yellow pine, Douglas fir, oak and chestnut are used. The planks may be laid either at right angles with the axis of the bridge or diagonally, the latter method making a floor which will be much stiffer. Planks should not be laid lengthwise of the bridge except under special conditions. They should usually be laid with the heart side down. A plank floor is supported upon steel or wooden stringers, spiking pieces being bolted to the steel stringers. It is not customary to crown a single plank floor, but if two thicknesses are used, a crown is more necessary.

WOOD BLOCK PAVEMENTS are in use in the more thickly settled districts. The blocks are usually about 3 or 4 in square and 6 to 10 in long and should always be treated with preservatives. They are usually laid upon a cushion of sand, asphalt, cement mortar or tar pitch resting upon a sub-base of wood or concrete. The wooden base is usually from 3 to 6 in in thickness and is either treated with preservatives or water-proofed in some way, and the joints made tight. The concrete base is usually supported by a buckle plate floor or by a reinforced concrete slab floor, or by concreting between I-beams. A longitudinal expansion joint 1 or 2 in in width should be provided next to the wheel guard.

STONE BLOCK PAVEMENT is durable but expensive, and very heavy. It is used when traffic is extremely heavy. It is laid on a cushion

of sand, and should have the joints filled with tar pitch. A concrete base is a common method of support altho sometimes the wooden base is used. Stone makes a much better foothold for horses than the other surfaces.

BRICK PAVEMENT is much lighter and less noisy than stone and is cheaper than wood block pavement. The method of laying is similar to wood-block.

CEMENT-CONCRETE may be used directly as a wearing surface. Its construction will be obvious. Sometimes a concrete surface is protected by a bituminous surface coating.

Specifications. Altho Art. 4 gives an outline of several specifications which include floors, the following paragraphs, being more complete in themselves, give further data.

Wooden Joists. Wooden floor joists shall be spaced not more than 2½ ft centers, and shall lap by each other so as to have a full bearing on the floorbeams. Their width shall not be less than 3 in, or ¼ the depth of joist. When spaced not more than 2 ft centers, one joist shall be considered as carrying ½ of the concentrated live load.

Steel Joists. Steel beams when used as joists shall have a depth of not less than 1/30 of the span, and 1/20 of the span when used as track stringers. When a single thickness of plank flooring is used the spacing of steel joists shall not exceed 2 ft 6 in, centers; when a heavier floor is used this limit may be 3 ft. When spaced not to exceed 2-ft centers, one joist shall be considered as carrying ½ the concentrated load; when spaced more than 2 ft and not more than 3 ft, one joist shall be considered as carrying ⅔ of the concentrated load.

Floor Beams. All floor beams shall be rolled or riveted steel girders, rigidly connected to the trusses at the panel points, or may be placed on the top deck bridges at panel points. Floor beams shall preferably be square to the trusses or girders.

Connections. All steel joists and stringers shall preferably be attached to the floor beams by means of connecting angles, altho in ordinary country bridges of CLASS D the joists may be decked on top flange of floor beams. In case shelf angles, stiffened with vertical angles, are used, the rivets in such angles and stiffeners may be counted as carrying end shear.

Solid Floor. For city and suburban bridges, a solid floor, consisting of wooden blocks, brick, stone blocks, sheet-asphalt, etc, on a concrete bed, is recommended. For this case the floor shall consist of buckle plates or corrugated sections or other satisfactory reinforcement, and a waterproof concrete, bituminous or Portland cement mortar, bed not less than 3 in thick for the roadway and 2 in thick for the footwalk, over the highest point to be covered, not counting rivet or bolt heads. The floor shall be laid with a slope of at least 1 in in 10 ft. Buckle plates shall not be less than 5/16 in thick for the roadway and ¼ in thick for the footwalk. The crown of the plates shall not be less than 2 in. For solid floor the curb holding the paving and acting as a wheel guard on each side of the roadway shall be of stone or steel projecting about 6 in above the finished paving at the gutter. The curb shall be so arranged that it can be removed and replaced when worn or injured. There shall also be a metal edging strip on each side of the footwalk to protect and hold the paving in place. Pavements consisting of wooden blocks may rest upon a wooden floor, consisting of planks laid transversely and at least 4 in thick. The type of block and method of laying shall be approved by the engineer.

Plank Floor. For single thickness the roadway planks shall not be less than 2½ in thick for oak, southern yellow pine and chestnut or 3 in for white pine, spruce and Douglas fir, nor less than 1/12 of the distance between centers of joists, and shall be laid transversely with ¼-in openings and securely spiked to each joist. All plank shall be laid with heart side down. When an additional wearing surface is required, it shall be 1½ in thick, and the lower planks of a minimum thickness of 2½ in shall be laid diagonally with ½-in openings. Footwalk plank shall be not less than 2 in thick nor more than 6 in wide, spaced with ½-in openings. All plank shall be laid with heart side down, shall have full and even bearing on and be firmly attached to the joists, and shall be sawed in a straight line along the outside of roadway and walk.

Wheel Guards. Wheel guards of a cross-section of not less than 6 by 4 in shall

be provided on each side of the roadway. They shall be spliced with half-and-half joints with 6-in lap, and shall be bolted to the stringers or joist with ⅝-in bolts, spaced not to exceed 5 ft apart.

Wood Block Paving shall be laid on a plank base, secured to spiking pieces; all of which shall be of sound merchantable southern yellow pine, free from loose or unsound knots or other imperfections which would impair its strength or durability. All to be cut from sound live trees. The spiking pieces if laid on top of joists will be 6 in in width and not less than 4 in in depth. The under course of the floor will be of 3 in plank sized to an even thickness of not less than 2⅞ in and laid with close joints. All unavoidable openings to be thoroly calked with oakum or other suitable material. Upon this base will be laid the wood block paving .... inches in depth.

The PAVING BLOCKS will be truly rectangular in form and shall be dressed on all sides except the top and bottom, both of which shall be smoothly sawn. The blocks shall not vary in width or depth more than 1/16 in. Their width shall be the same for the entire job and must not be less than 3 nor more than 4 in. Their length shall not be less than 6 nor more than 10 in.

TREATMENT. The spiking pieces, planking and track ties shall be creosoted with 12, and the paving blocks with 18 lb of dead oil of coal tar per cu ft of lumber, injected by the pressure process in closed cylinders. The creosote oil shall have a specific gravity between 1.03 and 1.07 at 38° C (100° F). The blocks when ready for use shall not absorb water more than an average of 4½% of their dry weight after being heated at 38° C (100° F) during 12 hr and then placed under water 12 hr.

CONSTRUCTION. The blocks will be set on a cushion consisting of a heavy coat of coal tar paving pitch applied while hot to the planking. They must be set and tamped quickly before the pitch hardens. The joints must then be thoroly pitched and the surface flushed with an application of the hot paving pitch, until all joints are completely filled. The blocks will be set with the grain vertical and with close joints and in uniform courses at right angles to the center line of the bridge, in such a manner that the longitudinal joints will be broken at least 2 in. They must be forced together as close as possible by hand when laid and properly tamped to a firm bearing and uniform surface. An expansion joint of such width as directed by the engineer will be provided next to the wheel guards. The expansion joint to be finally filled with the paving pitch. A thin layer of dry sand will be spread over the finished surface if required by the engineer.

9. Reinforced Concrete Beam and Girder Highway Bridges

Reinforced Concrete Beam Bridges may be divided into two classes. First, those bridges of short span, not exceeding about 20 ft, and having only ordinary country highway traffic, which are reinforced concrete slabs bearing from 12 to 18 in on each abutment. Such slabs may be designed the same as the tops of reinforced concrete box culverts. The Connecticut standard design for this type of bridge for 16-ft span is shown in Fig. 36. The second class is made of similar reinforced concrete slabs, but bear not only on the abutments, but also on two or more reinforced concrete beams which in turn bear also on the abutments. The beams in this case are not loaded uniformly thruout their clear span. If the clear span of the beam is at least 1.5 times the clear distance between the beams, the maximum bending moment may be taken as if the beam were uniformly loaded and is found by the formula $M = wL^2/8$ where w is the load in pounds per foot and L is the clear span in feet. For less span of beam use the formula: $M = \frac{wL^2}{8}\left(1 - \frac{1}{3}\frac{L_s^2}{L^2}\right)$, where L_s is clear distance between beams. This result should be multiplied by 12 to get M in inch-pounds. To obtain the dimensions of the beam, a simple approximate formula is $bd^2 = M/100$, where b is the width of the beam, and d is the depth from the top of the beam to the middle of the reinforcing steel. Both b and d are in inches. A value for either b or d must be assumed and then the formula solved for the other.

Usually b should be about ½ to ⅔ as great as d. As d is depth to the steel, the total depth of the beam should be about $d + 1\frac{1}{2}$. The reinforcing steel is made up of round steel rods whose diameter is from ½ to 1 in. The

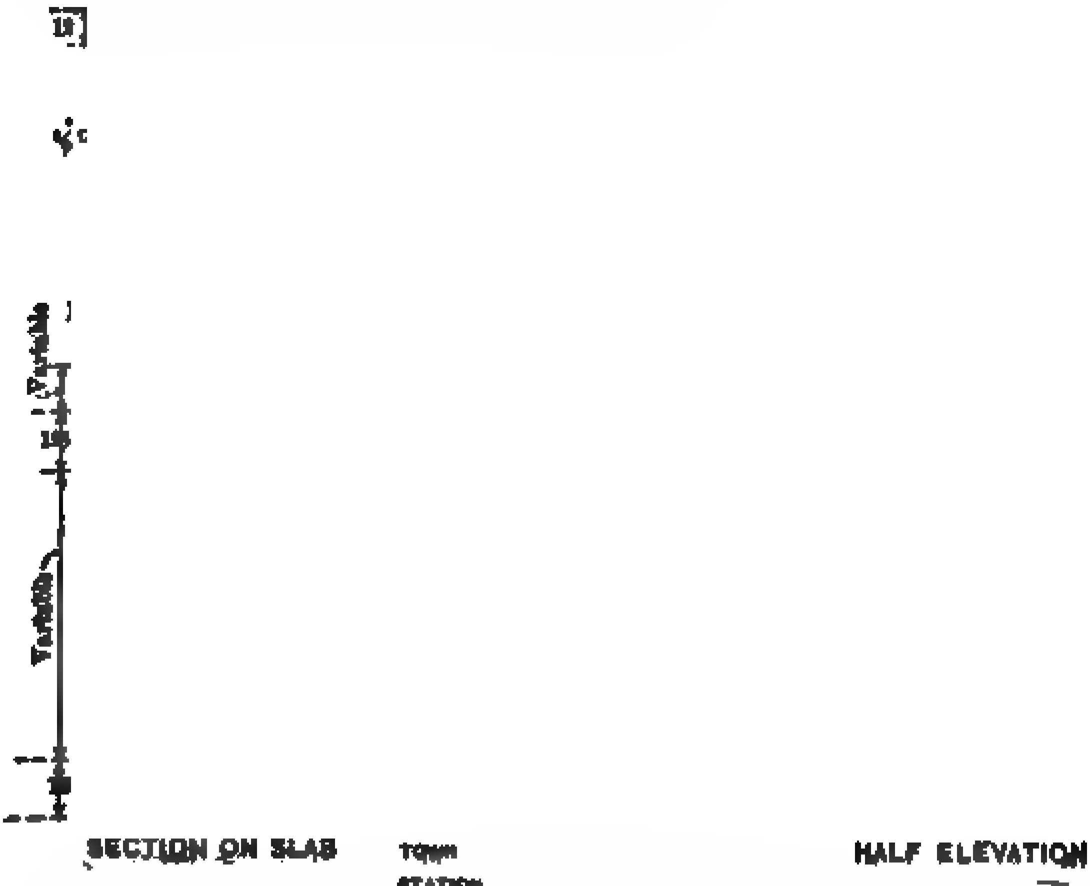

Fig. 36

total area of steel in the beam should be about $bd/100$. The rods may be spaced from 2 to 6 in center to center. Unless the clear span of the beam is at least 100 times the diameter of the reinforcing steel, twisted square rods should be used in place of plain round rods. About ⅓ of the rods in a

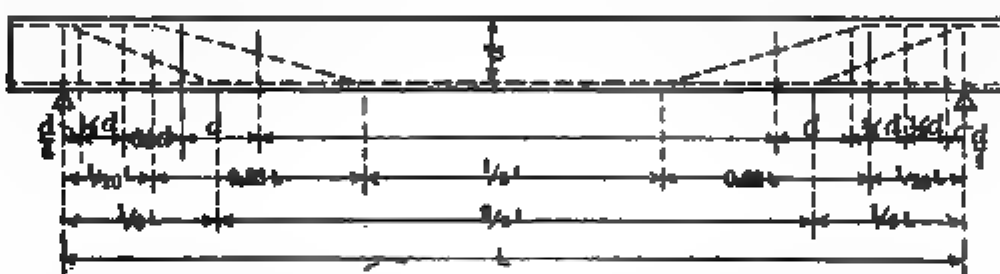

Fig. 37

beam or slab may be left horizontal thruout their entire length Half of the remainder should be bent up near the supports according to each of the two sets of dimensions in Fig. 37. The reinforcement is bent up at an angle of 30° to 45° until it reaches a point about 1 in from the top of the

beam, and then it is carried horizontally for the rest of its length. This diagonal reinforcement takes part of the diagonal tension resulting from vertical and horizontal shear. In addition to bending the rods, it is good practice to reinforce against diagonal tension by the use of stirrups. Stirrups are usually made of round or square steel rods about half the size of the longitudinal reinforcing bars. These rods are bent into complete rectangles, the ends being welded together. The dimensions of the rectangle are such that they will just surround the longitudinal and bent bars, that is they will be from 1 to 2 in inside of the surfaces of the beam. The stirrups should be wired firmly to the longitudinal bars. One stirrup is placed at a distance ¼ *d* from the support; the second ½ *d* from the first; the third ¾ *d* from the second; and the fourth *d* from the third (see Fig. 37). The reinforcing steel of a slab bearing on all four edges must be divided between the two directions. If, however, one dimension of the slab is more than 1½ times the other, the slab should not be considered as bearing on the ends of its long dimensions, but may be designed as a simple slab having a span equal to its shorter dimension. If the slab is square, ½ of the load is considered as carried by each set of reinforcement.

Taylor and Thompson (20) give the following table for the ratio of load carried by the shorter span:

Ratio of Length to Breadth of Slab	Ratio of Load Carried by Shorter Span	Ratio of Length to Breadth of Slab	Ratio of Load Carried by Shorter Span
1.00	0.50	1.30	0.80
1.05	0.55	1.35	0.85
1.10	0.60	1.40	0.90
1.15	0.65	1.45	0.95
1.20	0.70	1.50	1.00
1.25	0.75		

In case a slab or beam is continuous over three or more supports, the maximum [bend]ing moment will come over an interior support, and may be taken as $M = wL^2/12$, and tension will exist in the top of the slab at these points which must be provided for in the reinforcing.

Several Girder Spans may be used in place of a long steel bridge where the necessary piers would not result in a serious obstruction in the river bed. For principles of design, see Sect. 2, Art. 3, REINFORCED CONCRETE. For design of beams reinforced both top and bottom, see (20) and (21). They may also be used where arches would be impracticable on account of lack of the rigid foundations so necessary in arch construction. An investigation carried on by the Ill. Highway Comm. on a 40-ft thru girder concrete bridge shows that there is a great increase in rigidity of such structures. When the structure was over 3 years old, it took twice the load to produce the same deflection as at age of 90 days. It should be noted that in the design of reinforced concrete bridges, the dead weight may be several times that of the live load, and that the latter may cause very little proportional increase in stress in the materials. The 4th Report of the Ill. Highway Comm. calls attention to the following:

"The abutments for slab bridges are usually low and comparatively rigid, and as it has been found impracticable to provide sliding of the superstructure over the abutments, it has been found more economical for slab bridges to provide sufficient steel to take care of the combined dead load, live load and temperature stresses than to provide a more or less complicated and expensive expansion of low friction. In the

design of reinforced concrete girder bridges, however, it has been found more economical to provide for expansion at one end of the bridge than to use sufficient reinforcing steel to take care of the temperature stress in addition to the dead load and live load stresses. The use of an expansion device of low friction justifies the use of a higher dead and live load unit stress in the steel. This is of considerable importance particularly for long span reinforced concrete girders where the space available for packing the girder steel is limited. Two methods of providing for expansion in girder bridges have been used and both have proved satisfactory. (1) In this method, the wing walls of one abutment are entirely separated from the abutment wall proper, the latter being free to move at the top with the expansion or contraction of the superstructure. The wing walls are designed to be self-supporting. As girder spans designed by the Commission have so far been limited to 60 ft, the amount of movement either way from the normal is small and is taken up by deflection of the main wall or a slight rocking of the wall on the footing. (2) The present method of providing for expansion is to design the abutments and wings in the ordinary way, separating the superstructure completely from one of the abutments by a thick paper joint and supporting each girder at the free end on a single cast iron rocker of large diameter. The reaction is transmitted to the girder and abutment from the rocker thru planed structural steel plates stiffened with I-beams when necessary. The rocker surfaces in contact with the bearing plates are turned to insure perfect bearing on the plates. The diameter of the rocker is made proportional to the load imposed per lineal inch, in the same manner as is commonly used in proportioning roller nests for steel bridges. The upper and lower plates are bedded in the concrete of the superstructure and abutments. The rocker is located in a pocket built in the abutment. This pocket is filled with a soft asphalt to prevent the entrance of water or dirt and to protect the metal from corrosion. The rocker method of providing for expansion has proved very satisfactory, and is but little more expensive than the other method."

10. Reinforced Concrete Arch Highway Bridges

Types. There are two general types of reinforced concrete arch bridges, the spandrel filled arch and the open spandrel arch. In the spandrel filled arch the ring is continuous for the full width of the arch and the load on the rib is the weight of paving, earth fill, the rib itself, and the live load. The open spandrel arch may be built with a continuous arch rib or with two or more separate ribs, and the load is transferred either by columns or walls when the rib is continuous and by columns when there are separate ribs. In the open spandrel type, the bridge floor is usually the ordinary girder and slab construction, and is designed by the usual methods of reinforced concrete, namely, for its own dead weight, the weight of paving and fill and the specified electric car or road roller concentration. The rib is usually designed for an equivalent uniformly distributed load unless the span is so small that the concentrations of the moving load cause a worse condition. The typical problem which follows deals with an open spandrel arch. The spandrel filled arch is computed in the same way except a slice of arch 1 ft wide is used and all loads are for this width. Loads in this case are conveniently considered to act at center of divisions.

Shape of Arch Rib. The curve of the rib may be anything that fits the line of pressure. It is usually circular, three or five-centered, elliptic or even parabolic. The circular curve is usually satisfactory for open spandrel arches and the three-centered and elliptic curves are common and satisfactory for spandrel filled arches.

Loads. The dead load is the actual weight of the structure based on 150 lb per cu ft for reinforced concrete and 100 to 120 lb per cu ft of fill plus the weight of paving and track. Suitable live loads depend upon the location of the structure, city, suburban or country, and whether the bridge carries electric cars. All highway bridges should be designed to

carry a road roller. Equivalent uniformly distributed live loads for the arch ribs of highway bridges carrying electric cars as well as the loads on roadway and sidewalk are shown in Fig. 38 by Taylor and Thompson (20). Live loads for floors and columns are shown in Fig. 39.

Impact. There is no unanimity of opinion as to the proper impact allowance for highway arch bridges. It seems proper to vary the impact stress from zero in light country bridges without electric cars to not more than 50% in heavy city bridges with electric cars. A common formula is $I = S\dfrac{150}{300 + L}$ in which S = live load effect, due to moment, shear or stress; L = loaded length producing maximum effect; I = impact effect. Impact is more important upon the floor than upon the ribs.

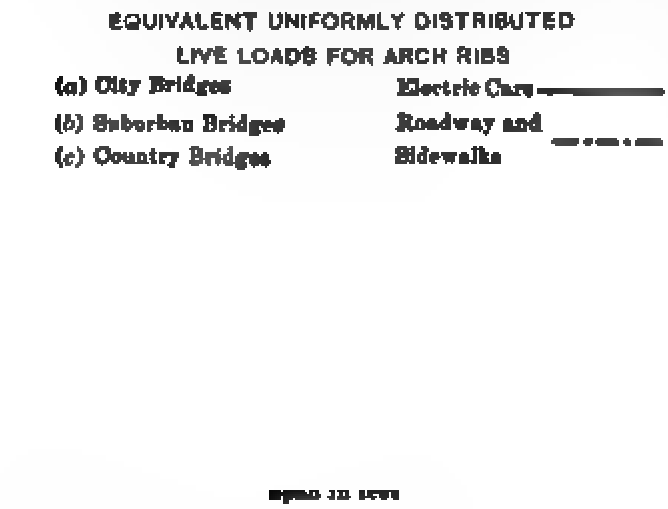

Fig. 38

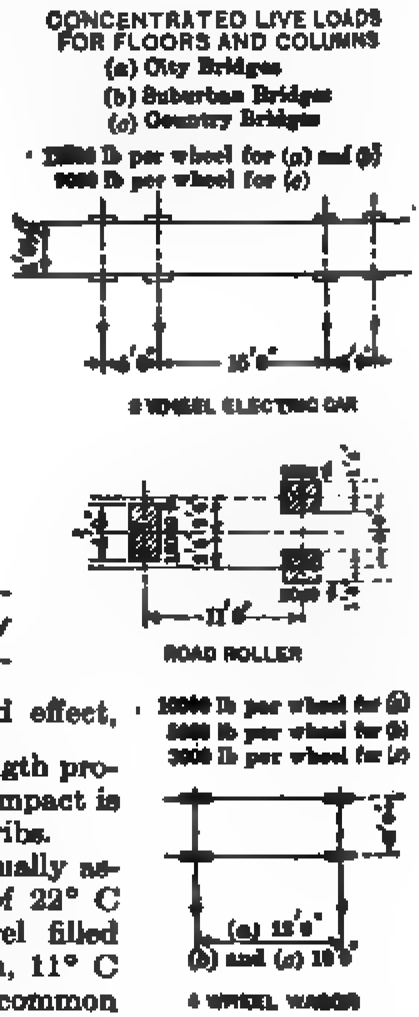

Fig. 39

Temperature. Open spandrel arches are usually assumed to have a variation of temperature of 22° C (40° F) above and below the mean. Spandrel filled arches are not subject to so large a variation, 11° C (20° F) above and below the mean being a common assumption. These figures apply in the northern part of the United States. If temperature stresses are not computed, the dead and live load compression stress in the concrete ought to be limited to about 500 lb per sq in.

Rib Shortening. Stresses due to rib shortening are similar to those due to a fall in temperature, and it is usually not necessary to compute them except in very flat arches. In a rib with ratio $\dfrac{\text{span}}{\text{rise}} = 5$, the effect is about 30% of that due to fall in temperature of 11° C (20° F) or 15% due to a fall of 22° C (40° F).

Materials. First-class 1 : 2 : 4 broken stone concrete ought to be used for all concrete above foundations. In many cases abutments or foundations may be 1 : $2\frac{1}{2}$: 5 or 1 : 3 : 6 concrete.

Unit Stresses. The unit stresses recommended by the Joint Committee on Concrete and Reinforced Concrete (24) are satisfactory for the slabs, beams and columns of open spandrel arch bridges. This Joint

Committee was composed of 28 representatives from the Am. Soc. C. E., the Am. Soc. Test. Mat., the Am. Ry. Eng. Assn., the Assn. Am. Portland Cement Mnfrs. and the Am. Concrete Inst. The recommendations of this Committee for allowable working stresses on plain and reinforced concrete are made in percentages of the ultimate compressive stress, developed in 28 days on cylinders 8 in in diameter and 16 in long. The recommended unit stresses for a 1 : 2 : 4 concrete, developing an ultimate compressive stress in 28 days of 2000 lb per sq in, are as follows:

Intensities of Working Stresses for Reinforced Concrete

Kinds of Stress	Percentage of 2000 lb	In Pounds per Square Inch
Compression on concrete in extreme fibres of beams	32.5	650
Compression on concrete in extreme fibres of continuous beams at supports	37.5	750
Concentric compression on a plain concrete pier, the length of which does not exceed four diameters	22.5	450
Bearing on plain concrete applied to a surface whose area is at least twice that of the loaded area	35.0	700
Concentric compression on a column reinforced with not less than 1% and not more than 4% of longitudinal bars only, the length of which is less than 12 diameters	22.5	450
Concentric compression on columns reinforced with not less than 1% and not more than 4% of longitudinal bars and with circular hoops or spirals not less than 1% of the volume of the concrete and in which $l/d=10$. (The effective area of a hooped column is the area within the circle enclosing the spiral hooping)	35.0	700
Punching shear on footings	6	120
Shear on concrete in beams with horizontal reinforcement only	2	40
Shear on concrete in beams with varying kinds of web reinforcement	4.5 to 6	90 to 120
Bond stress between concrete and plain bars	4	80
Bond stress between concrete and deformed bars	5	100
Bond stress between concrete and drawn wire	2	40
Tension and compression on steel in reinforcing bars		16 000

The Joint Committee makes no recommendations for working intensities of stress on plain or reinforced concrete arch ribs. The usual specifications give the following values for highway bridges: Compression on concrete in extreme fibers of arch ribs when live and dead loads only are considered, 500 lb per sq in. Compression on concrete in extreme fibres of arch ribs when stresses due to dead and live loads, temperature and rib shortening are considered, 600 per sq in. These two values are, however, seldom consistent inasmuch as stresses due to temperature and rib shortening are frequently much larger than the difference of 100 lb.

Temperature stresses vary a great deal in different arches so that the omission of such stresses can not be recommended. It is better practice to compute the stresses due to the dead and live loads, temperature (40° F

in northern part of the United States) and rib shortening, in which case it is believed that ribs having $l/d = 10$ can properly be designed by using a maximum compressive working stress of 700 lb per sq in. l = unstiffened length of rib and d = smallest transverse dimension of rib. If both impact and temperature stresses are considered it is permissible to use $f = 750$ lb per sq in compression in 1 : 2 : 4 broken stone concrete.

Position of Live Load for Maximum Stresses in Arch. For the rib itself, approximately the worst position is when half the bridge is covered with live load. This is due to largely increased moments. In a series of arches the worst condition of loading for a pier occurs when the longer span is covered with live load and the shorter one carries dead load only.

The Method of Design outlined below is the ELASTIC METHOD adopted to fixed ends since the great majority of concrete arches are of this type. For derivation and full discussion, see Turneaure and Maurers' Principles of Reinforced Concrete Construction (21).

Approximate Thickness of Arch Rib at Crown. It is convenient to start the design knowing the approximate thickness of the arch rib at the crown. A common formula is given by F. F. Weld, applying to spandrel filled arches only, as follows: $d = \sqrt{L} + 0.1\,L + 0.005\,W + 0.0025\,D$, in which d = depth of arch rib at crown in inches, L = clear span in feet, W = live load in pounds per square foot uniformly distributed, D = dead load of material above the crown of the arch per square foot in pounds. The arch rib is ordinarily from one and one half to twice as thick at

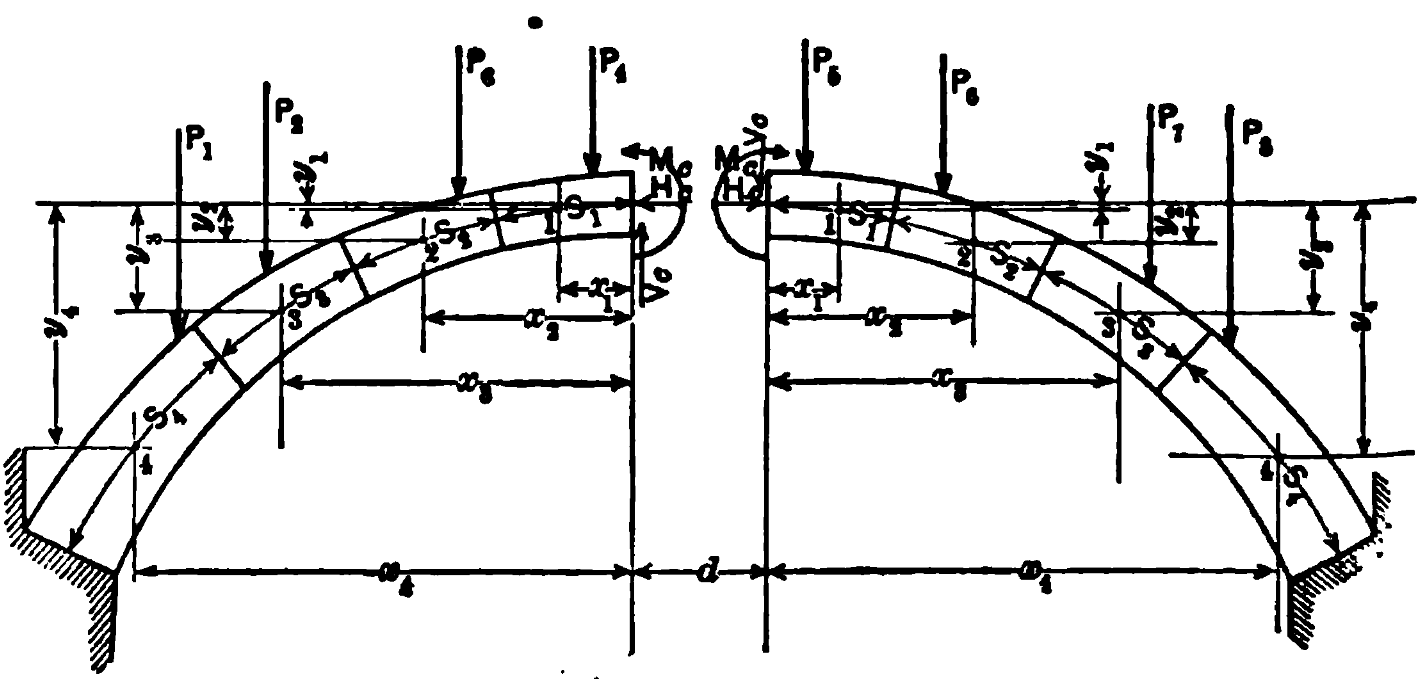

Fig. 40

the springing line as at the crown. No formula can be given to determine the tentative size of the rib in open spandrel arches. When conditions are known it is usually possible to compute the approximate thrust at the crown by moments from which a trial thickness and width can be selected.

Fill Over Crown. In solid spandrel filled highway arch bridges, the earth fill over the crown is usually equal to or somewhat greater than the thickness of the rib itself.

Locating the Line of Pressure. Fig. 40 represents any arch cut at the crown with the two halves moved apart an appreciable distance d, so that they can be considered temporarily as cantilever beams fixed at the spring-ing lines. From the following equations, the values of the thrust, moment, shear and eccentricity at the crown are determined in terms of x, y, m,

and n, summed up about the centers of the divisions 1, 2, 3, etc. as shown below.

$$H_c = \frac{n \Sigma m y - \Sigma m \Sigma y}{2[(\Sigma y)^2 - n \Sigma y^2]} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$M_c = -\frac{\Sigma m + 2 H_c \Sigma y}{2n} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$V_c = \frac{\Sigma(m_R - m_L) x}{2 \Sigma x^2} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

$$e_c = \frac{M_c}{H_c} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

$$M = m + M_c + H y \pm V_c x \quad . \quad . \quad . \quad . \quad . \quad (5)$$

(+) sign in the last term of equation 5 is to be used on the left half of arch and (−) sign is to be used on the right half, when live load is on left hand half of arch;

in which H_c = the horizontal thrust at the crown;

M_c = the bending moment at crown, assumed positive when the stress on the upper fiber is compression and negative when the stress in upper fiber is tension;

V_c = the shear at the crown, assumed to be positive when acting upward on left half of arch as shown in Fig. 40;

M = actual moment at any section;

m = the bending moment at any point, assuming arch to be cut as in Fig. 40 and computed as tho the half were a cantilever beam, that is, m_{L2} = the moment of loads P_3 and P_4 about point 2, center of the second division on the left from crown; m is always negative;

n = the number of divisions in one half the arch determined below.

x, y = the horizontal and vertical coordinates respectively of any point on the arch axis, referred to the crown as the origin, all values for both halves being positive;

e_c = the eccentricity of the line of pressure from the arch axis at the crown, positive when above and negative when below;

I = moment of inertia of any cross-section = $I_c + r I_s$;

r = ratio E_s/E_c, usually 15;

S = length of any division of the arch ring.

In equations 1, 2, 3, 4 and 5, V_c is positive when live load is on left half only and equals zero when the live and dead loads are equal and symmetrically placed on the two halves. The quantities y, y^2, and x^2 are for one half the arch only; Σm is for the entire arch and equals $\Sigma m_R + \Sigma m_L$; $\Sigma(m_R - m_L)\, x$ is a summation in which m_R and m_L are the bending moments, as cantilever beams, at corresponding points in both halves which have equal abscissas x. $\Sigma\, m\, y$ is for the entire arch and equals $\Sigma(m_R + m_L)y$.

Equations 1, 2, and 3 require that I/S must be a constant, because I/S has been cancelled from the theoretical equations on this assumption. Each half of the arch is divided into the same number of divisions, and the centers of corresponding divisions are numbered alike from the center out. To avoid too large divisions toward the springing lines, arches of ordinary span require from seven to ten divisions in each half. The cen-

ters of these divisions are the points about which the moments m are computed and have no connection with the points at which loads are applied. For convenience only it is customary in the spandrel filled arch to assume the loads to act at the centers of the divisions. If it happens that a load comes exactly at the center over the crown, it is considered that half the dead load acts on each half, and, if loaded with live load over one half, then the whole of the live load goes to the loaded side. In showing these loads, as in Fig. 41, it is likely to save trouble if loads $K\ L$ and $L\ M$ are separated slightly at the crown.

Cost of Reinforced Concrete Arches. Ordinary spandrel filled arch bridges from 40 to 100 ft span carrying electric cars, and having 1 : 2 : 4 broken

Typical Problem. Fig. 41 represents an open spandrel highway

Fig. 41

arch bridge carrying 2000 lb live load per lin ft of bridge or 1000 lb live load per lin ft of rib. The floor design is not given. From the completed de-

sign the various loads including floor, earth fill, columns, arch rib and live load over left half only were taken as follows:

Loads on One Arch Rib

Load Designation	Dead, lb	Live, lb	Total, lb
A – B	79 000	15 000	94 000
B – C	55 000	10 000	65 000
C – D	55 000	10 000	65 000
D – E	49 000	10 000	59 000
E – F	47 000	10 000	57 000
F – G	40 000	10 000	50 000
G – H	30 000	7 500	37 500
H – I	20 000	5 000	25 000
I – J	20 000	5 000	25 000
J – K	20 000	5 000	25 000
K – L	10 000	2 500	12 500
L – M	10 000	.....	10 000

P – Q	30 000	.....	30 000
Q – R	40 000	.....	40 000
R – S	47 000	.....	47 000
S – T	49 000	.....	49 000
T – U	55 000	.....	55 000
U – V	55 000	.....	55 000
V – W	79 000	.....	79 000
Total	.....	.....	940 000

Divide each half of the arch axis so that I/S = a constant. See Fig. 41*b*. The size of the rib, the amount of reinforcement and its position must be tentatively assumed. In this case the rib is 5 ft 6 in deep at the springing line and 3 ft deep at the crown with a constant horizontal thickness of 3 ft 6 in. Eight 1-in square rods are used in each flange thruout, 6 in from center of rods to edge of rib at the springing line and 3 in from center of rods to edge of rib at crown. Lay off the horizontal line *ad*, (see Fig. 41*b*), equal to one half the length of arch axis, that is, from springing line to crown. Select not less than four points on the arch axis at approximately equal distances apart, springing line, crown and two intermediate points, and compute, as explained below, the transformed moments of inertia of the normal cross-sections of the rib at these points. At some convenient scale erect perpendiculars at *a*, *b*, *c*, and *d*, the corresponding points in Fig. 41*b*, so that half the values of I for each point is on each side of the line *a b c d*. Then draw symmetrical curves thru the extremities of these perpendiculars. Commencing at *a*, draw an inclined line *a e*, then the perpendicular *e f*. Continue this process until the last inclined line passes thru *d*. It may require several trials to secure a suitable number of divisions. The horizontal intercepts S_1, S_2, S_3, etc, on *a b c d* now represent the lengths of the divisions of the arch such that I/S = a constant when I for any division is measured perpendicularly between the curves at the middle point of the division. Divide each half arch axis into divisions equal to S_1, S_2, etc, numbering the middle points of the divisions from the crown toward the springing line as in Fig. 41*a*.

The transferred moment of inertia is:

$$I = I_c + r\,I_s$$

in which I_c = moment of inertia of the concrete about the horizontal axis thru the center line of gravity of the cross-section.

I_s = moment of inertia of the steel about the same axis, usually taken as $A_s\,d^2$.

A_s = area of steel in arch rib.

d = distance from center line of gravity of cross-section to center of steel.

r = the ratio of the moduli of elasticity of steel and concrete = E_s/E_c = 15 by usual specifications.

The computations for the location of the line of pressure are all tabulated in Table I. The origin is taken at the crown with the X and Y axis as shown. Columns 2 and 3 give the values of the x and y coordinates of the center points of the divisions corresponding to the numbers in column 1. Columns 6 and 7 give the moments about the center points of the divisions, assuming the arch cut as in Fig. 40, and considering each half to be a cantilever beam fixed at the springing line. The results in column 8 are products of the sum of columns 6 and 7 multiplied by y for the corresponding points and all quantities are negative. Column 9 gives results for the difference between moments m_R and m_L for any point multiplied by x for the corresponding point, these results being positive when the live load is on the left half.

The quantities H_c, V_c and e_c are now computed from the Table by means of equations 1, 2, 3, and 4. The line of pressure can now be located by graphical methods as follows: Lay off the vertical loads from left to right on the line $a\,b\,c$—w, as in Fig. 41c. From 1, draw a horizontal line = H_c = 560 000 lb and at its left extremity erect a perpendicular = V_c = 13 550 lb, upward in this case because V_c is positive. z is now the correct pole position and rays are drawn from z to $a\,b\,c$—w. Scale the distance $e_c = -0.128$ ft downward from origin or arch axis at crown, and thru this point draw a line between the continuation of the load lines for loads $K\,L$ and $L\,M$, parallel to $l\,z$ in Fig. 41c. This process is continued by drawing segments of the line of pressure between the load lines parallel to the corresponding rays. The letter at the extremity of the ray always indicates the space in which the corresponding segment is drawn. H_c and V_c are plotted to the same scale as the vertical loads. The length of any ray represents the stress along the corresponding segment of the line of pressure, the last two segments of which locate the resultant arch pressure on the abutments. The remaining columns of Table I afford an accurate check on the graphical construction. Columns 10 and 11 are self-explanatory. Columns 12 and 13 are computed from equation (5) and are the true moments at the corresponding points. Columns 14 and 15 give the vertical intercepts from arch axis to line of pressure. The moment at any point as shown in columns 12 and 13 divided by H_c equals the vertical intercept at the corresponding point, and these intercepts can be immediately used to check the position of the line of pressure.

Temperature Stresses. The following formulas are used to determine the stresses due to temperature:

$$H_t = \frac{E\,I}{S} \times \frac{c\,t\,L\,n}{[2(n\,\Sigma\,y^2 - (\Sigma\,y)^2)]144} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (6)$$

$$M_{tc} = -\frac{H_t \Sigma\,y}{n} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (7)$$

Table I

	Dimensions in Feet									Moments in Foot-Pounds

Σ	216 4	42 0	9914 75	566.40	−25 509 425	−20 524 900	−627 187 000	+268 631 800						
					Σ m = −46 034 325									

$$H_c = \frac{n\Sigma my - \Sigma m \Sigma y}{2\left[(\Sigma y)^2 - n\Sigma y^2\right]} = \frac{7\,[-627\,187\,000] - [-46\,034\,325 \times 42]}{2\,[\overline{42}^2 - 7 \times 566.4]} = 560\,000 \text{ lb}$$

$$M_c = -\frac{\Sigma m + 2H_c\Sigma y}{2n} = -\frac{-46\,034\,325 + 2 \times 560\,000 \times 42}{14} = -72\,000 \text{ ft-lb}$$

$$V_c = \frac{\Sigma (m_R - m_L)\,x}{2\Sigma x^2} = \frac{268\,631\,800}{2(9914.75)} = +13\,550 \text{ lb}$$

$$e_c = \frac{M_c}{H_c} = \frac{-72\,000}{560\,000} = -0.128 \text{ ft}$$

$$e_t = \frac{M_{tc}}{H_t} = -\frac{\Sigma y}{n} \quad \ldots\ldots\ldots\ldots\ldots \quad (8)$$

$$M_t = M_{tc} + H_t y \quad \ldots\ldots\ldots\ldots\ldots \quad (9)$$

in which H_t = thrust at crown due to temperature, positive for rise and negative for a fall in temperature;

M_{tc} = moment at crown due to temperature and always opposite in sign to H_t, in foot-pounds;

M_t = moment at any point due to temperature;

e_t = eccentricity of temperature thrust measured down from the origin in feet (a horizontal line drawn below arch axis at crown by an amount e_t cuts the arch axis at two points where moments due to temperature are 0, and this line locates the true position of the temperature thrust);

c = coefficient of expansion, usually taken as 0.000 006 per degree F;

L = span of arch axis measured between springing lines;

t = change in temperature in degrees F, either plus or minus.

In equations (6) to (9) inclusive, E, I, L, and s are in inches, H_t in pounds, M_t in foot-pounds, e_t in feet, y in feet, and $[2(n\Sigma y^2 - (\Sigma y)^2)]$ is in feet. The latter expression is taken from Table I, and is the same as in the denominator for value of H_c except the signs are changed to give a positive value to H_t for a rise in temperature.

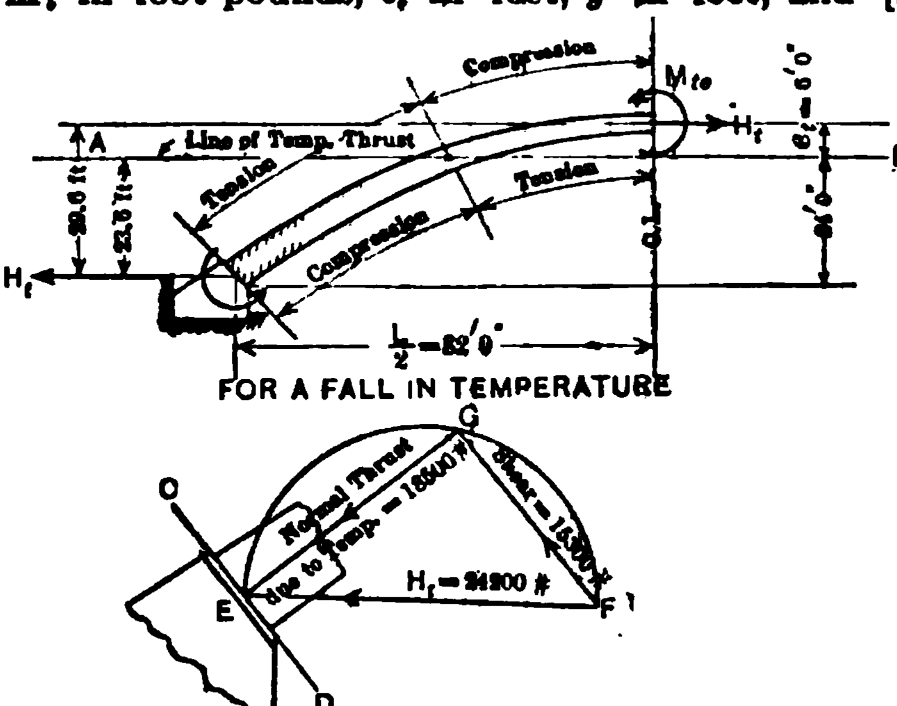

Fig. 42

Fig. 42 represents the conditions for a fall in temperature, moments and thrusts having opposite signs from those shown for a rise in temperature.

In the illustrative problem, I/S = 2300, E = 2 000 000, c = 0.000 006, L = 164 ft = 1968 in, n = 7, $t = \pm 40°$ F., $2(n\Sigma y^2 - (\Sigma y)^2)$ = 4392 sq ft. And for a rise in temperature.

$$H_t = \frac{2\,000\,000 \times 2300\ (0.000\,006 \times 40° \times 1968 \text{ in} \times 7)}{4392 \times 144} = 24\,200 \text{ lb}$$

$$M_{tc} = -\frac{24\,200 \text{ lb} \times 42}{7} = -145\,200 \text{ ft lb}$$

$$e_t = -\frac{42}{7} = -(6 \text{ ft}) \text{ at springing line from equation (8).}$$

Moment due to a rise in temperature, M_{ts} = − 145 200 ft lb + 24 200 × 29.6 ft = + 570 000 ft lb, or more directly M_{ts} = 24 200 lb × 23.6 ft = + 570 000.

The normal thrust on any cross-section due to temperature can be deter-

mined by the method of Fig. 42, in which H_t is resolved into two components, normal and parallel respectively to the cross-section. The temperature thrust is taken as the diameter of a semicircle $E F$. Then any line drawn from the extremity of the diameter as $E G$ parallel to a normal on any cross-section, to its intersection with the circle, measures the normal thrust at the section, which, in the case shown, is at the springing line. The line $G F$, always at right angles to $E G$, measures the shear on the section due to temperature. The normal thrust at any section due to vertical loading is obtained from Fig. 41c by resolving that ray, that cuts the section in question, into two components at right angles such that one is normal to the section.

Stresses in the Arch Ring. The stresses in the arch ring are obtained by combining the effects of thrust and moment at the given section. When temperature stresses are considered, it is convenient to combine the moments due to vertical loads and to temperature and to similarly combine the thrusts, using the resulting values for moment and thrust in the equations. If the line of pressure is everywhere within the middle half, middle third for plain concrete, the usual formulas for combined stress are accurate enough. These are as follows:

$$f_c = \frac{N}{A_c + r A_s} \pm \frac{N e u}{I_c + r I_s} \qquad (10)$$

$$f_s = \frac{r N}{A_c + r A_s} \pm \frac{r N e v}{I_c + r I_s} \qquad (11)$$

in which f_c = unit stress in extreme fiber of concrete;
f_s = unit stress in extreme fiber of steel;
N = normal thrust on cross-section;
u = distance from center line of gravity of cross-section to extreme fiber of concrete;
v = distance from center line of gravity of cross-section to extreme fiber of steel;
r = ratio E_s/E_c and usually = 15;
The denominators of equations (10) and (11) are respectively the transformed areas and moments of inertia of the cross-sections, the latter of which can be scaled directly from Fig. 41b;
Ne = the moment at the section, equals normal thrust times eccentricity, but when temperature moments have been combined it is more convenient to substitute directly the total moment for Ne.

The formulas involve the assumption that every fiber in the cross-section carries its proportion of the stress. When therefore, a solution shows a tensile stress in concrete of about 150 lb per sq in, about the ultimate strength of concrete, the formulas begin to be unreliable. If the line of pressure is very eccentric or the temperature thrust is very large, it may be found that these formulas do not apply and others suitable for such condition may need to be used. Such equations are, however, difficult to solve without proper curves and cannot be given here. The equations and accompanying curves are given by Taylor and Thompson (20). The usual equations are satisfactory for the illustrative example, but it will be found that they reach this limit of usefulness in the solution for stresses at the springing line.

Stresses at crown of arch. See Fig. 41a.

Thrust due to vertical loads	$= +$	560 000 lb
Thrust due to rise in temperature of 22° C (40° F)	$= +$	24 000 lb
Total thrust at crown		584 200 lb
Moment due to vertical loads	$= -$	72 000 ft lb
Moment due to rise in temperature of 22° C (40° F)	$= -$	145 200 ft lb
Total moment at crown	$= -$	217 200 ft lb
	$= -$	2 606 400 in lb

Transformed area at crown $= A_c + r\,A_s = 1736$ sq in
Transformed I at crown $= I_c + r\,I_s = 213\,400$ sq in
$u = 19.5$ in $\qquad v = 16$ in.

Maximum compressive stress in lower fiber of concrete from equation (10):

$$f_c = \frac{584\,200 \text{ lb}}{1736 \text{ sq in}} + \frac{2\,606\,400 \text{ in lb} \times 19.5 \text{ in}}{213\,400 \text{ in}^4}$$
$$= 336 \text{ lb per sq in} + 239 \text{ lb per sq in}$$
$$= 575 \text{ lb per sq in compression in concrete.}$$

Minimum compression stress, f_c, on upper fiber at crown:

$$f_c = 336 \text{ lb per sq in} - 239 \text{ lb per sq in}$$
$$= 97 \text{ lb per sq in compression in concrete.}$$

Maximum compression stress in steel at crown in lower fiber from equation (11):

$$f_s = \frac{584\,200 \text{ lb} \times 15}{1736 \text{ sq in}} + \frac{15(2\,606\,400 \text{ in-lb} \times 16 \text{ in})}{213\,400 \text{ in}^4}$$
$$= 5040 \text{ lb per sq in} + 2940 \text{ lb per sq in}$$
$$= 7980 \text{ lb per sq in in compression in steel.}$$

Minimum compressive stress in steel at crown in upper fiber:

$$f_s = 5040 \text{ lb per sq in} - 2940 \text{ lb per sq in}$$
$$= 2100 \text{ lb per sq in compression in steel.}$$

Stress at springing line of arch (see Fig. 41*a*). On account of greater eccentricity, the right side is selected.

Thrust due to vertical loads	$= +$	712 000 lb
Thrust due to rise in temperature of 22° C (40° F)	$= +$	18 500 lb
Total thrust at springing line	$= +$	730 500 lb
Moment due to vertical loads	$= +$	670 000 ft lb
Moment due to rise in temperature of 22° C (40° F)	$= +$	570 000 ft lb
Total moment at springing line	$= +$	1 240 000 ft lb
	$= +$	14 880 000 in lb
Transformed area $= A_c + r\,A_s$ at springing line	$=$	2996 sq in
Transformed $I = I_c + r\,I_s$ at springing line	$=$	1 170 000 in^4

$u = 33$ in $\qquad v = 27.5$ in.

Maximum compression stress in concrete at springing line in upper fiber from equation (10):

$$f_c = \frac{730\,500 \text{ lb}}{2996 \text{ sq in}} + \frac{14\,880\,000 \text{ in lb} \times 33 \text{ in}}{1\,170\,000 \text{ in}^4}$$
$$= 244 \text{ lb per sq in} + 420 \text{ lb per sq in}$$
$$= 664 \text{ lb per sq in compression in concrete.}$$

Maximum tensile stress in concrete at springing line in lower fiber,

$$f_c = 244 \text{ lb per sq in} - 420 \text{ lb per sq in}$$
$$= 176 \text{ lb per sq in in tension.}$$

Maximum compression stress in steel at springing line in upper fiber from equation (11):

$$f_r = \frac{15(730\ 500 \text{ lb})}{2996 \text{ sq in}} + \frac{15(14\ 880\ 000 \text{ in lb} \times 27.5 \text{ in})}{1\ 170\ 000 \text{ in}^4}$$

$$= 3660 \text{ lb per sq in} + 5240 \text{ lb per sq in}$$

$$= 8900 \text{ lb per sq in compression in steel.}$$

Maximum tensile stress in steel at springing line in lower fiber:

$$f_s = 3660 \text{ lb per sq in} - 5420 \text{ lb per sq in}$$

$$= 1580 \text{ lb per sq in tension in steel.}$$

Without considering temperature, the maximum compression stress in concrete at the springing line is found to be 465 lb per sq in and no tension exists. These stresses are satisfactory for the sections selected. If the unit stress should prove to be too large or too small, the shape of the arch rib would need to be revised and new computations made.

11. Stone Masonry Arch Highway Bridges

The masonry arch has been largely superseded by the reinforced concrete arch. Only brief mention will here be made of some of the characteristics of such arches, and it should be noted that no attempt has been made to give any principles of design. For complete discussions, reference should be had to works on masonry and arches, see (2), (12a) and (16b).

Parts of an Arch. Baker (2) gives the following definitions: ABUTMENT, a skewback and the masonry which supports it. BACKING the masonry outside and above the arch stones, which usually has joints horizontal or nearly so. CROWN the highest part of the arch. EXTRADOS, the convex curve which bounds the outer extremities of the joints between the voussoirs. HAUNCH, the indefinite part of the arch between the crown and the skewback. INTRADOS, the concave line of intersection of a vertical plane with the lower surface of the arch. KEYSTONE, the center or highest voussoir or arch stone. RISE, the vertical distance between the highest part of the intrados and the plane of the springing lines. SKEWBACK, the inclined surface or joint upon which the end of the arch rests. SPAN, the horizontal distance perpendicularly between the lowest joints of the arch. SPRINGING LINE, the inner edge of the skewback. SPANDREL, the indefinite space between the extrados and the roadway. The wall at the end of the arch above the extrados is called the spandrel wall; and the material between the end walls and above the extrados is called the spandrel filling. VOUSSOIR, one of the wedge-shaped stones of which the arch is composed; also called an arch stone. The voussoirs which show at the ends of the arch are called RING STONES; and those which do not thus show are called ARCH SHEETING. If the intrados is a semicircle, the arch is a FULL CENTERED ARCH, and if less than a semicircle, it is a SEGMENTAL ARCH.

Methods of Failure. An arch may fail: (1) By crushing; (2) by sliding of one voussoir on another, or by sliding upon the foundation; (3) by rotation about some joint. Settlement of the foundation is a common primary cause of failure. Baker (2) states that to prevent (1) " the line of resistance should intersect each joint far enough from the edge so that the maximum pressure will be less than the crushing strength of the masonry "; to prevent (2) " the angle between the line of resistance and the normal to any joint should be less than the angle of repose, angle of friction, for those surfaces; that is to say, the tangent of the angle between the line of resistance

and the normal to any joint should be less than the coefficient of friction"; to prevent (3) "it is necessary that the line of resistance shall everywhere lie between the intrados and the extrados." For good design, the line of resistance should be inside the middle third of the arch ring.

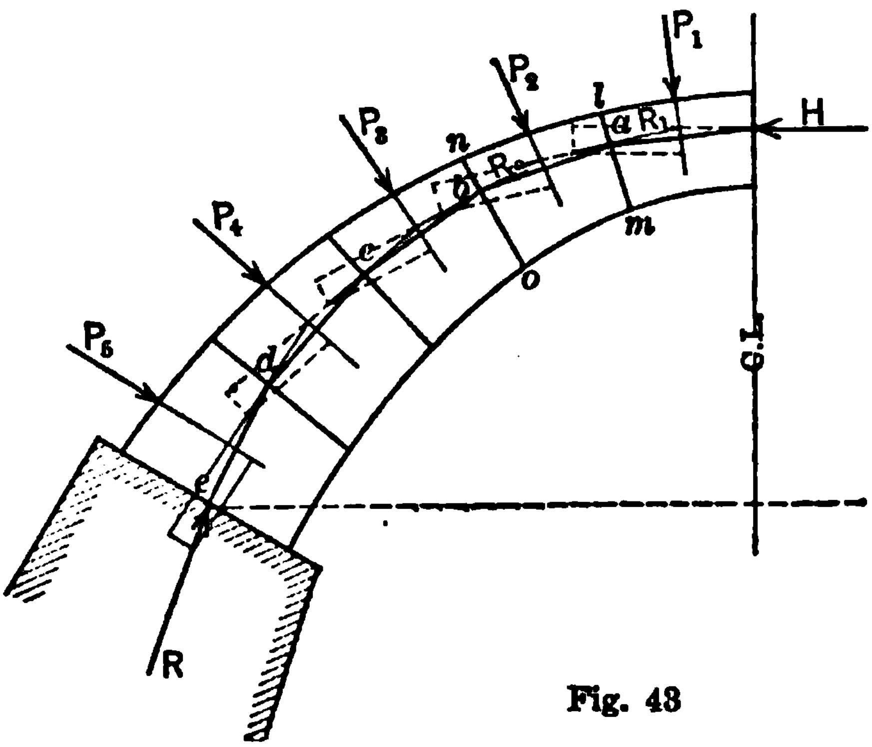

Fig. 43

Line of Resistance. Fig. 43 shows the forces acting upon ½ of a masonry arch. This arch has been divided into imaginary sections by lines as shown. Assuming that the arch is symmetrically loaded and that all forces are known in magnitude, direction and line of application, H and P_1 may be combined giving R_1 which intersects l m at a. R_1 is combined with P_2 giving R_2 which intersects n o at b, etc. The points a, b, c, d, e are called centers of resistance and the polygon developed by connecting them is called the line of resistance, which approaches a curve as the number of divisions of the arch is increased.

CULVERTS

12. Location and Design of Culverts

Culverts are usually placed on the line of natural water courses, at the bottom of the sag in the profile of the original ground. Nearly always, they are placed under fills, and occasionally under cuts. They should cross under the highway as nearly as possible at right angles to its center line. This saves in cost.

The Size of a Culvert depends upon the rate of rainfall per hour for a period of time equal to the time required for water to reach the culvert from the farthest part of the drainage area. That is, if all the rain falling on an area reaches a culvert in 10 min, and a maximum rainfall of ½ in in 10 min is recorded, then the rate of rainfall for that culvert would be 3 in per hr. For large areas, the maximum rainfall in 1 hr is used. The size depends on the size of the drainage area, and also upon its shape and configuration; thus a nearly square or circular area requires a larger culvert than one which is long and narrow, one with well defined valleys requires a larger culvert than one consisting of a flat slope. The size depends also upon the amount of vegetation and cultivation; trees and brush by retarding the flow of water and cultivation by making the soil more absorbent may decrease the size of culvert necessary. In warm climates, size depends upon porosity of soil. On extremely sandy soils 30 to 50% of rainfall will reach the culvert; on heavy clays, 90 to 100%. Long heavy rains will saturate any soil until nearly the entire rainfall will run-off to the culvert. Frozen ground will give 100% run-off, to which should be added allowance for rain melting snow.

Formulas. Probably the two formulas which have been used more than any others for size of culverts are as follows: In Atlantic states, Myer's

formula $A = C \sqrt{\text{ACRES IN DRAINAGE AREA}}$; in Mississippi valley states, Talbot's formula; $A = C \sqrt[4]{(\text{ACRES IN DRAINAGE AREA})^3}$. In both formulas, A is the cross-section of the culvert in square feet; C varies, in Myer's formula, from 1 for rolling country and 1.5 for hilly ground to 4 for mountainous or rocky ground; and in Talbot's, from $\frac{1}{6}$ for long, narrow valleys to 1 for steep, rocky ground. The following method is recommended for determining the size of culvert: $V = C\sqrt{s}$, where V = velocity of water in miles per hour, C varies between 10 where contours are straight and 40 where there is a well defined valley, and s is the ratio of slope. If by this formula V is greater than 7, use $V = 7$. $T = D/V$, where T is the time in hours required for water to reach the culvert from the most remote part of the area, and D is the distance from that point to the culvert in miles. $Q = \frac{1}{2} r \sqrt[4]{S A^3}$, where Q is the discharge in cubic feet per second, r is the rate of rainfall in inches per hour for time T, S is slope in percent, A is acres in area. The cross-section of the culvert equals $Q/10$.

13. Construction of Culverts

For Pipe Culverts under low fills, use two or three pipes side by side in place of one larger pipe. Use pipe culverts up to capacity of two 24-in pipes. Be sure that conditions at the lower end of the culvert will carry off water as fast as the culvert discharges. Lay all pipe culverts nearly level from upper end for half its length, then slope at least one in ten to lower end, rounding off change of slope. Settlement of fill is thus taken care of. The bottom of the inside of the pipe at each end should be at the elevation of the natural soil. All pipe culverts have at least 1 ft of fill over them, and where traffic causes very heavy loads, 2 ft. If the fill is not over 10 ft, double strength, vitrified sewer pipe may be used. This comes in lengths of 24 in, 30 in or 36 in dependent on the size of the pipe. If the soil is firm, excavate about 1 ft wider than the size of the pipe and about 8 in below the pipe grade. Fill in with gravel, bedding the pipe thereon, but use care that the pipe bears entirely upon its barrel and not on its bell ends. Lay the pipe to the true line and grade beginning at the lower end of the culvert and facing the bell ends towards the upper end of the culvert. Caulk joints with oakum and fill in the remainder of the joint with a mixture of one part Portland cement and one part sand. In backfilling, fill slowly in thin layers and tamp thoroly on both sides of the pipe. As pressure on top of the pipe tends to burst out the sides, do not tamp hard directly over it.

Cast Iron Pipes are always better than vitrified pipe culverts and the extra cost is more than compensated for by their greater permanency. They are constructed similarly except that the joints of the cast iron pipes are filled with lead, instead of cement mortar, which gives a much more pliable joint.

Orrock's "Railroad Structures and Estimates" (18) gives the following weights for cast iron pipe, and cost at $35 per ton:

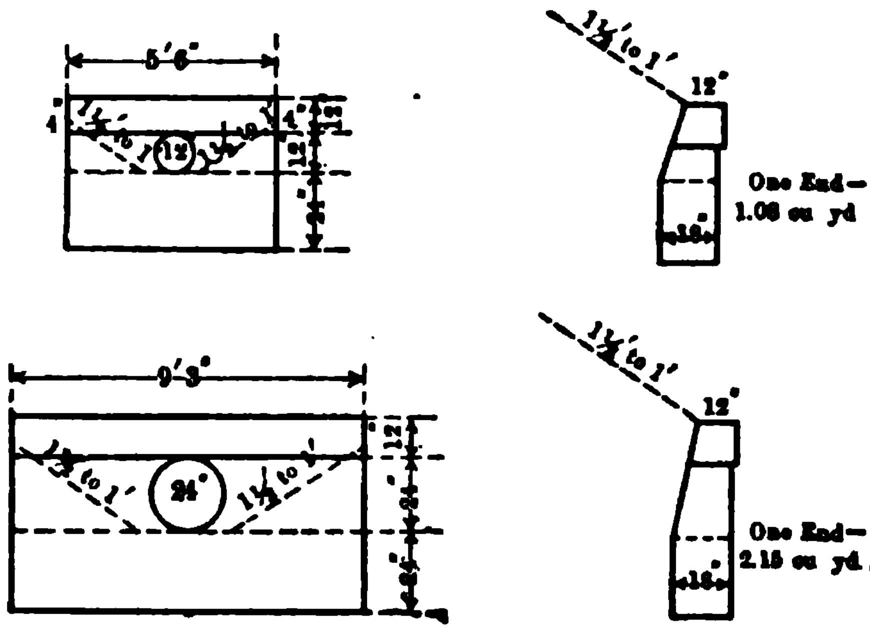
Diameter	Weight per Ft	Cost per Ft
8 in	53 lb	$0.93
10 in	73 lb	1.28
12 in	95 lb	1.66
14 in	119 lb	2.09
16 in	147 lb	2.57
18 in	176 lb	3.08

Corrugated Metal culverts have come rapidly into use in highway construction, as corrugation gives a very high strength in proportion to the

weight of the material. Corrugated metal culverts come from the factory in sections of semi-circumference 2 ft in length, taking two sections to form a complete pipe. It is made in sizes of from 8 in to 72 in in diameter. Trenching is done as for other pipe culverts except that there are no bell ends to be cared for. Owing to its light weight, the culvert may be put in place with less trouble than with any other pipe. Backfilling should be done with just as great care as is used for other pipes.

Corrugated metal culverts are also made in one piece complete circular sections in lengths up to 36 ft. These lengths are fastened together by corrugated metal collars covering adjoining ends and bolted. All corrugated metal culverts should be galvanized; the coating should contain not less than ¾ oz of zinc per sq ft of each side of the metal. The approximate cost per lin ft is about as follows: 8-in, 54 cents; 12-in, 72 cents; 18-in, $1.04; 24-in, $1.44; 36-in, $2.84; 48-in, $4.14.

Concrete Pipe. Altho both plain and reinforced concrete culvert pipe is on the market, the reinforced pipe is much better, because of its lighter weight for a given strength. This pipe is made in a variety of sizes, the smaller sizes being reinforced with wire mesh and the larger with hoops and longitudinal bars. Care must be used in laying as the hoop reinforcement is near the inside of the pipe at the top and bottom and near the outside at the sides of the pipe. These pipes are cast in 2½ and 3-ft lengths and have bell and spigot joints, which are filled with cement mortar, one part Portland cement and one part sand.



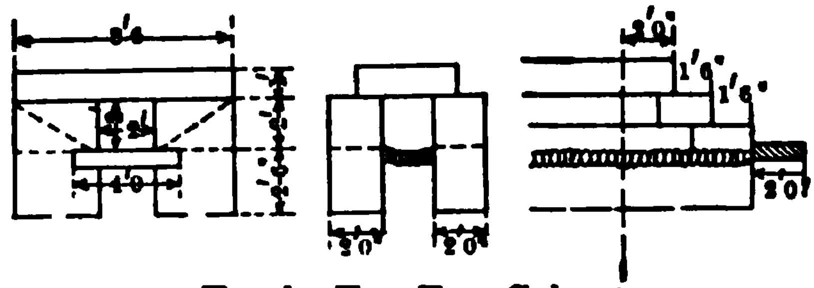
Notes: 8-in Pipe Culvert, one end, 4 ft 2 in long; 0.77 cu yd.
10-in Pipe Culvert, one end, 4 ft 10 in long; 0.92 cu yd.
16-in Pipe Culvert, one end, 6 ft 10 in long; 1.42 cu yd.

Fig. 44

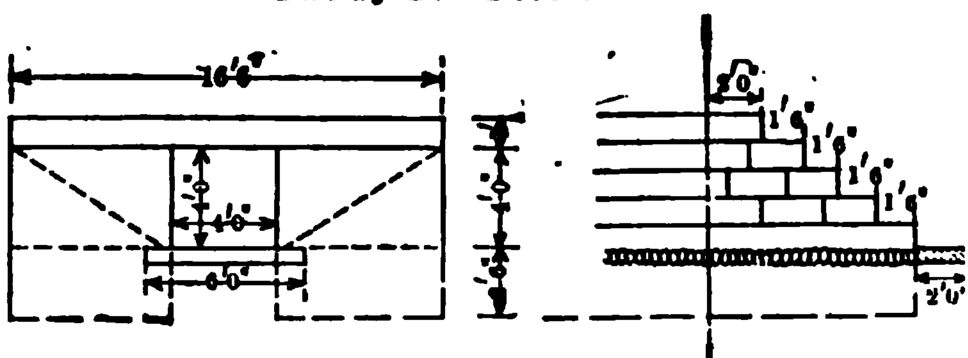
End Walls for Pipe Culverts. Massachusetts standard concrete end walls for pipe culverts are shown in Fig. 44. It is estimated that end walls cost about $8 per cu yd of concrete in place.

Stone Box Culverts may be used where large blocks of stone are available and where the use of concrete materials would require a long haul. The cover stones must be large enough to overlap for at least 1 ft on each side wall. This type of culvert may be built double in order to increase its capacity, the center wall being built with a cut-water end. The side and center walls, which should have a thickness of not less than 0.4 their height, are built of large stone laid in Portland cement mortar and extend at least 2½ to 3 ft below the natural surface of the ground, with spread footings if necessary, to secure a proper bearing. The floor of the culvert is paved with cobblestones set on end, so that their tops are in the same general plane, and grouted with Portland cement mortar. Massachusetts standards for stone box culverts with end walls and also with stepped ends are shown in Fig. 45.

Reinforced Concrete Culverts. For spans of 4 to 10 ft thru small fills, use plain concrete sides and reinforce the top and bottom by embedding old railroad rails in 10 to 12 in of concrete. Place rails 12 in centers, except under heavy traffic, in which case the rails in top of culvert should be 8 or 10 in centers, the top to bear at least 1 ft on each side wall. The side walls should be 2 ft thick at the top and should batter on the earth side to a thickness at the bottom of not less than 0.4 their height. If soil is firm, make the floor of paving stone as for a stone box culvert. If soil is not firm, make the floor similar to the top, but place rails both transversely and longitudinally. This is not strictly reinforced concrete, as the load is carried entirely by the rails, the concrete merely protecting the rails and making them act together.



Two by Two Foot Culvert

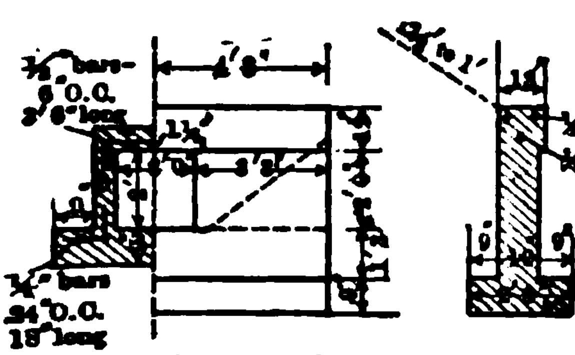


Four by Four Foot Culvert

Notes: 2 by 2 ft Culvert, one end: Above foundation, 1.59 cu yd; foundation, 1.20 cu yd; apron, 4 by 2 by 0.5 ft, 0.15 cu yd; walls, covers, paving, 0.864 cu yd; paving, 8 in deep.
2 by 2 ft Culvert, end stepped, one end: Above foundation, 1.7 cu yd; foundation, 2.10 cu yd; apron, 4 by 2 by 0.5 ft, 0.15 cu yd; walls, covers, paving, 0.864 cu yd.
4 by 4 ft Culvert, one end: Above foundation, 4.92 cu yd; foundation, 2.31 cu yd; apron, 6 by 2 by 0.5 ft, 0.22 cu yd; walls, paving, 1.11 cu yd; covers, 0.22 cu yd; paving, 12 in deep.
4 by 4 ft Culvert, end stepped, one end: Above foundation, 4.0 cu yd; foundation, 4.15 cu yd; apron, 6 by 2 by 0.5 ft, 0.22 cu yd; walls, paving, 1.11 cu yd; covers 0.22 cu yd.

Fig. 45

Baker (2) gives the following FORMULAS for the design of regular reinforced concrete box culverts: For top and bottom: $M = S^2 (100\,H + L)$; for side walls, $M = 1.4\ (2H\,h^2 + h^3)$; where M = maximum bending moment in inch-pounds, S = clear span in feet, H = height of embankment above inside of culvert top in feet, L = live load in pounds per square foot, h = clear height of culvert in feet. Considering 1 ft of length of either top, bottom or side as the beam, the thickness may be found from: $d^2 = M/f_s\,p\,j$ or $d^2 = M/f_c\,kj$. Ordinary values of $k = 3/8$, $j = 7/8$ and $p = 0.008$ to 0.015. Working values of f_s = 12 000 to 15 000 and of f_c = 400 to 650. As reinforcement should be bedded 2 in in concrete, thickness = $(d + 2)$ in. Area of steel reinforcement per foot of length = $M/f_s\,j\,d$.

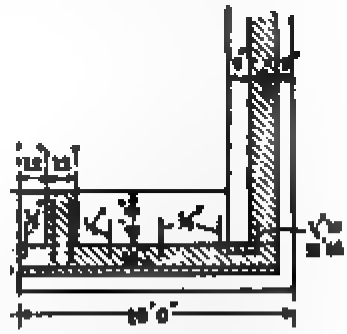


Notes: Reinforced Concrete 2 by 2 ft Culvert. Data per foot of culvert section: Concrete, 0.2346 cu yd; steel, ¼-in bars, 0.318 lb and ½-in bars, 5.95 lb.
Data for one end: Concrete, 1.72 cu yd; steel bars, one ½-in bar, 8 ft long, two ¼-in bars, 8 ft long, two ¼-in bars, 2 ft long; weights, ½-in bars, 6.8 lb and ¼-in bars, 4.24 lb.

Fig. 46. Two by Two Foot Reinforced Concrete Culvert

Massachusetts standard reinforced concrete box culverts are shown in Figs. 46 and 47.

Reinforced concrete culverts, as well as all other kinds vary exceedingly in cost according to location and conditions of construction. A culvert in one place may cost twice or three times what its exact duplicate may have cost elsewhere, but a fair average for estimating the cost of reinforced concrete culverts is about $14 per cu yd of concrete. Inasmuch as reinforced



Notes: Reinforced Concrete 6 by 6 ft Culvert. Data per foot of culvert section: Concrete 0.727 cu. yd; steel, $\frac{1}{2}$-in bars, 21.248 lb and $\frac{1}{4}$-in bars, 3.824 lb.

Data for one end: Concrete, 3.02 cu yd, steel bars, six $\frac{1}{2}$-in bars, 9 ft long, two $\frac{1}{2}$-in bars, 8 ft 5 in long, one $\frac{1}{2}$-in bar, 7 ft long, four $\frac{1}{2}$-in bars, 11 ft long, four $\frac{1}{4}$-in bars, 8 ft 5 in long, two $\frac{1}{4}$-in bars, 7 ft long, fourteen $\frac{1}{4}$-in bars, 2 ft long; weights $\frac{1}{2}$-in bars, 103.553 lb and $\frac{1}{4}$-in bars, 16.041 lb. All sizes calculated for deformed square bars of medium steel.

Fig. 47. Six by Six Foot Reinforced Concrete Culvert

concrete box culverts are now built with a clear space as great as 20 ft, there is little advantage in using arch culverts, as they require more head room and the expense of forms is much greater than for concrete box.

Timber Box Culverts. In country where timber is very plentiful and it is difficult to bring in pipe or materials for concrete, timber box culverts may be used. They should be built large enough to build pipe culvert inside before the expiration of the life of the timber. Double 4 by 4 ft box is the largest capacity that it is economy to build. Side walls should be built of 12 by 12 in timber, laid lengthwise of culvert, and drift bolted together. The cover should be of 8 by 12 in timber, laid with 8-in vertical, placed across the culvert, with a 12 by 12 in every 4 or 5 ft let in so that the lower 4 in may act as a strut between the side walls. The bottom should be of 3 by 12 in plank laid longitudinally thru the culvert on 2 by 12 in battens placed at intervals of about 5 ft.

RETAINING WALLS

14. Design of Retaining Walls

Efforts to obtain formulas for the design of retaining walls have been made by generations of engineers, but owing to almost innumerable combinations of conditions met with, it is practically impossible to give theoretical formulas for their design. All theories are based on the assumption that the surface or rupture of retained earth is a plane. It is a well-known fact that ordinary soils may be dug out to a vertical plane and will stand in that condition for a short time due to cohesion of the particles composing

it. First failure will leave the surface concave upwards. Weather will change this surface near the top to convex upwards. The surface of rupture, therefore, is not a plane. Theories are also based on the assumption that the point of application of resultant pressure is at one-third of the height of the wall above the bottom. In wet soils the point of application will be not much higher than this owing to large water pressure; but with drier soils, the point will be higher, dependent upon the quality of retained material, and may be as high as the middle of the wall. Ordinarily this point is about 0.4 of the height above the bottom. The most used theory. Rankine's, assumes the direction of pressure as parallel to the surface of retained earth. As this would make a given wall more stable when retaining earth with surcharge than with earth with level top, it is, of course, untenable. All experiments show that the direction of pressure is not horizontal. Experiments have proved that there is a very material amount of friction between the earth and the back of the wall. This does not appear in any theoretical formulas, but certainly increases the stability of a wall. In general, then, the cohesion of the particles making up the retained earth, and the adhesion of these particles to the back of the wall make theoretical formulas of little value for ordinary retaining walls used in highway work. If a wall is built to retain a highway in fill, the material comprising the fill, and the method of placing it may be such as to decrease the load against the wall. Such fills should be made in layers, sloping away from the wall thus decreasing both earth and water pressures. Also pressure is decreased by providing proper drainage for water. If the retained roadway is higher than the top of the wall, the extra height is known as SURCHARGE, and the wall must be heavier in such a location. Heavy highway traffic should be figured as so much surcharge, and consider soil to weigh 100 lb per cu ft. Retaining walls used where the highway is in cut will often be heavily surcharged, as sloping ground may rise for a considerable distance above the wall. Such cases require walls of maximum thickness.

Retaining walls may fail (1) by SLIDING OR SHEARING along a plane that is horizontal or nearly so; (2) by OVERTURNING about the front edge of the base; or (3) by CRUSHING at the front edge of the base or other horizontal joint. It is generally conceded that a well-built stone masonry wall that will not fail by overturning, is strong enough not to fail by sliding either on its base or any horizontal joint. As most retaining walls are now built of concrete, and are keyed to the foundation, the resistance to sliding is materially increased and is amply sufficient even with light reinforced concrete walls.

In order not to overturn or crush, the THICKNESS OF THE WALL at the base should be about 35 to 40% of its height, and the slope or step back of the wall to a thickness of 2 ft at the top of the main wall. For ordinary surcharge make the thickness at base 50% of height. The coping at the top should not be considered as part of the retaining wall. The face of wall may be vertical, altho a batter of ¾ or 1 in to the ft gives a better appearance. Walls built of first-class material and of above thickness should not crush. Most failures of retaining walls are due to poor foundations and not to failure of the wall itself. As most soils are at least slightly compressible, unless sufficient spread is given to footing courses, the extra pressure at the front edge of the base may cause undue settlement and a tilting of the wall. If great enough, this unequal settlement may cause actual failure in a wall which otherwise would be perfectly safe. Therefore if the soil is at all questionable, pile foundations should be used. Under

the above conditions small walls are built to lean slightly toward the earth, thus throwing the center of pressure on the base back of the center.

The most COMMON SECTION for a retaining wall is as given above, namely, nearly vertical face and sloping or stepped back. Also, as noted above, considerable saving in material may be made by sloping both face and back of wall back towards the retained earth. In this latter section, care should be used to keep the vertical thru the center of gravity within the base. This section is not advised for high walls because of the heavy action of frost. Stability of these sections is dependent entirely upon the weight of the masonry. With reinforced concrete, the weight of part of the retained earth makes up for decrease in masonry.

Good drainage is very important. Wet soil is much heavier than dry. Wet clay has but little cohesion and the wall has to resist the thrust of a much greater mass of earth. The force of water freezing back of the wall is liable to cause serious trouble. To drain off the water, build a 3-in pipe thru the wall near the bottom at intervals of from 10 to 20 ft. If the earth back of the wall is sand or gravel, water will reach these outlets easily, otherwise a vertical layer 15 to 20 in thick composed of broken stone or clean gravel should be placed back of the wall.

15. Reinforced Concrete Walls

Nearly all such walls for highway work are of the CANTILEVER TYPE, having a base of concrete somewhat wider than half the height of the wall and from 1 to 2 ft thick. From near the middle of this base rises the wall, leaving nearly half of the base covered with the retained earth, the weight of which helps to resist overturning. For high walls, over 20 or 25 ft, or where foundation and wall must not cross the property line, a COUNTERFORTED WALL may be used. This differs from the cantilever in that the wall rises from one edge of the base, the remainder being loaded with retained earth. Also, counterforts, vertical walls at right angles to face of wall, are placed about every 8 ft which are of the same thickness as the main wall at the base but taper to nothing at the top.

To Design Reinforced Concrete Retaining Walls, first assume the section for a plain concrete retaining wall according to the rules given above. Assume that this plain concrete wall is a dam, retaining a fluid of such weight as to cause the resultant pressure to pass thru the front end of the middle third of the base. Taking 1 ft of length of this plain concrete wall, the moment of its weight is its weight times the distance from the front end of the middle third of the base, taken as the center of moments, to the point where the vertical thru the center of gravity cuts the base. This resisting moment $= 1/6\, w\, h^3$, where h is height of wall and w is weight of fluid as above stated. Solve this for w. Now assume that the reinforced concrete wall, together with the retained earth vertically above the back end of the concrete base, is a dam, retaining fluid having a weight of w lb per cu ft. Design for 1 ft of length of wall. Assume weight of concrete as 150 lb per cu ft and the weight of earth above back part of base as 100 lb per cu ft. Find center of gravity of these and draw a vertical line thru the center of gravity. Thru a point $1/3\, h$ above the base draw a horizontal line. From intersection of these lines lay off to some scale on the vertical line the weight of concrete and earth as given above, and on the horizontal line the value of $\frac{1}{2}\, w\, h^2$. If the resultant of these forces cuts the bottom of the base within its middle third the wall will be safe from overturning or crushing. As reinforced concrete walls are thin, the matter of horizontal shear is

important. The force tending to shear is $\frac{1}{2}\, w\, h^2$ for each foot of length. Assuming concrete to have a safe resistance to shearing of 25 lb per sq in, the least thickness at the bottom of a vertical wall to safely resist shear is $w\, h^2/600$ in per ft of wall. Even reinforced concrete walls are usually much thicker than this.

16. Construction of Retaining Walls

Stone Masonry retaining walls should be built of stones free from imperfections and durable in courses not less than 12 in thick. To secure proper transverse bond, every fourth stone should be a header and at least as wide as thick. The headers should extend entirely thru the wall unless it is more than 4 ft thick. The stretchers should be at least $1\frac{1}{2}$ times as wide as thick, and at least 4 ft long. The beds and vertical joints should be about $\frac{1}{2}$ in thick, dressed and squared at least 10 in back from the face of wall, care being taken that a vertical joint in one course does not come within 8 in of the vertical joint in the course next below and spalls should be used where needed. Backing of wall should consist of large stones, well bedded on horizontal beds without spalls. The wall should be completely covered by a coping composed of large stones not less than 8 in thick, unless the wall is over 4 ft thick. This coping must not overlap the plane of the back of the wall, as frost will lift it.

Plain Concrete. Moorefield (55) gives the following data for plain concrete retaining walls, see Fig. 48: $W = H/12$, never less than 10 in; $b = 4/10H$, never less than 10 in; for $H < 6$ ft, B need never be greater than $4/10\ H + 1$; for $H > 6$ ft, $B = 4/10\ H + 0.75$ rock foundation, $B = 4/10\ H + 1$ good gravel foundation, $B = 4/10\ H + 1.25$ medium gravel foundation, $B = 4/10\ H + 1.5$ good clay foundation, $B = 4/10\ H + 1.75$ medium clay foundation.

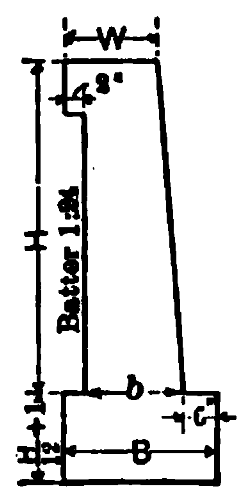


Fig. 48

Forms for plain concrete walls should be made of green lumber which will not swell from contact with wet concrete. The boards should be 1 in thick, tongued and grooved. For the back of the wall, it is not necessary to plane either side but the face of the boards against face of wall must be planed, and better results are obtained if the faces in contact with the concrete are also planed as the forms will come off cleaner. The lumber must be free from all loose knots, the best being used for the face of the wall. Straight parallel edges are necessary to make tight joints. Studding, 2 in by 4 in for low walls and 2 in by 6 in for higher walls, should be spaced 2 ft center to center. Forms for the backs of walls are ordinarily braced from the ground, for even small failure in braces will have bad results, if only on the appearance of the walls. Forms for faces of walls should be braced as follows: Fasten small 2-in wooden blocks inside each form, one opposite the other, having $\frac{5}{8}$-in holes thru forms and blocks; from block to block have piece of $\frac{1}{2}$-in pipe to separate forms; thru the holes in the forms and thru the pipe pass $\frac{3}{8}$-in iron rods, threaded at each end, and long enough to pass thru the entire form and have nuts screwed up outside of forms at both ends. When forms are removed, remove rods and fill up holes in wall formed by the 2-in wooden blocks with rich mortar. Before placing forms in position, coat their faces with soft soap to permit of forms being removed earlier, thus allowing the concrete to set more rapidly. This also permits surfacing face of wall while concrete is still green. Heavy oil or other grease may be used in place of soft soap; but latter is

not injurious to cement and is easily soluble in water when form is cleaned. Before placing concrete in forms, clear out all sawdust, pieces of wood, etc. Use 1:3:6 concrete for base of wall, 1:2½:5 concrete for main wall, and 1:2:4 concrete for coping. The Portland cement must meet the ordinary commercial tests, the sand must be coarse and clean, and the gravel or broken stone clean, that is free from dust and organic matter. The pieces making up the gravel or broken stone should be of hard and durable materials and of spherical or cubical shape, not long and thin, the stone for plain concrete being not greater than 3 in in any dimension. In large masses of concrete, however, large stones, called PLUMS, may be inserted to decrease the amount of concrete necessary. Such stones should be rammed into the concrete in order to bring them into intimate contact with the concrete on all sides and must not be within 2 in of any form or of each other. Their total volume should not exceed 30% of the volume of the wall. Mix cement and sand dry until color is uniform, then add stone and water and mix until each stone is thoroly coated with mortar.

Contraction. Concrete contracts when setting due largely to drying out of water. To prevent a wall from cracking in an unsightly manner, provide vertical contraction joints every 25 to 40 ft by building wall to full height in sections of this length and fastening on the inside of the end of the form a 2 by 4 in vertical scantling so that, when form is removed, there will be a vertical groove in end of section. In casting the next section, this groove will be filled with a concrete tongue. The bond between the new concrete and the old will be so poor that contraction will break it, but the tongue and groove will maintain the strength of the wall. Unless concrete is put in place rather dry and in cold weather, there is little probability of its ever having a tendency to increase in volume. Such an expansion would call into play the compressive strength of the concrete, which in practically all cases would be sufficient to withstand the stresses without danger of buckling.

Reinforced Concrete Walls. Moorefield (55) gives the following data for reinforced concrete retaining walls.

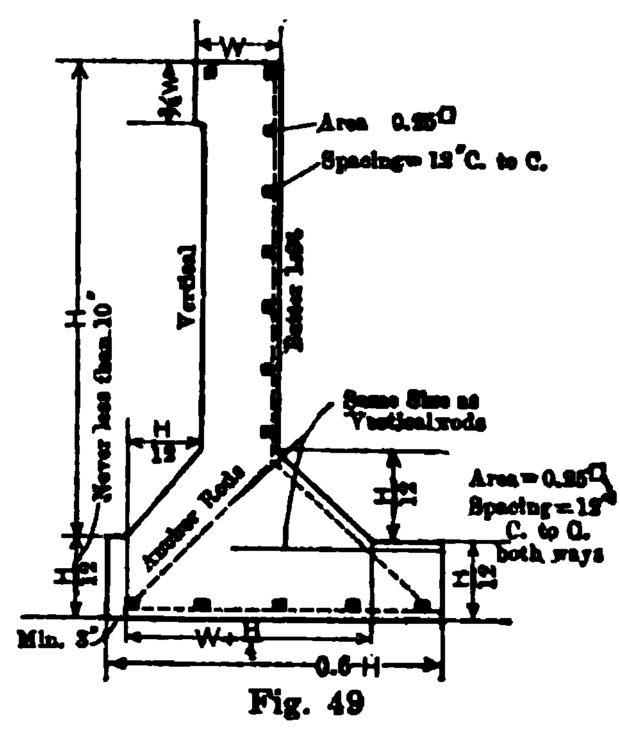

Fig. 49

H	W	Vertical Bars Size	Vertical Bars Spacing
2 ft	0 ft 7 in	½ by ½ in	12 in *c* to *c*
4 ft	0 ft 7 in	½ by ½ in	12 in *c* to *c*
6 ft	0 ft 7 in	½ by ½ in	12 in *c* to *c*
8 ft	0 ft 8 in	½ by ½ in	10 in *c* to *c*
10 ft	0 ft 9 in	½ by ½ in	8 in *c* to *c*
12 ft	0 ft 10 in	⅝ by ⅝ in	8 in *c* to *c*
14 ft	1 ft 0 in	⅝ by ⅝ in	6 in *c* to *c*[1]
16 ft	1 ft 0 in	¾ by ¾ in	6 in *c* to *c*[1]
18 ft	1 ft 2 in	¾ by ¾ in	5 in *c* to *c*[2]
20 ft	1 ft 4 in	¾ by ¾ in	4 in *c* to *c*[3]

[1] Alternate bars end 8 ft up from base.
[2] Alternate bars end 9 ft up from base.
[3] One-third of bars end at 4 ft and one-half at 10 ft up from base. The note (3) regarding spacing in 20-ft wall would probably better read one-third of bars end at 7 ft and one-half of the remainder at 14 ft up from base.

Forms. Even greater care is necessary in the building of forms for reinforced concrete than for plain concrete on account of the thin masses of

concrete. All reinforced concrete should be a 1:2:4 mixture, the stone used being not greater than 1 in in any dimension. Reinforcement should be firmly held in place by fine strong wire connecting various rods to each other and to the forms. At joints of longitudinal reinforcement, lap rods at least 25 times the least dimension of the rod and bind thoroly with strong ductile wire. In placing concrete use great care not to displace the reinforcement, and to have the concrete come into intimate contact with the reinforcement on all sides.

FOUNDATIONS

17. Bearing Power of Soils

Wherever the abutments or piers of a bridge are to be placed, and in a lesser degree, wherever a retaining wall is to be placed, the soil should be thoroly examined as to its ability to sustain the load. The soil at the site of a retaining wall may be examined by driving sections of gas-pipe by hand from a scaffold. Great changes of conditions of the soil are obtainable in this manner. For bridge foundations, it is better to obtain samples of the soil at various depths by means of a post-hole auger. But these samples are not entirely satisfactory as they do not give the condition of compression of the soil in place. For important bridges, probably the best way to determine the bearing power of the soil is to excavate a well to a considerable depth, if possible to the bottom of the estimated footings, and load a vertical timber 12 in square.

Bed Rock will undoubtedly carry any load which may be placed upon it under these conditions. But if the surface of the rock slopes to any considerable degree, great care must be used to bond the masonry to it in such a way that it cannot possibly slide. The lowest portions of concrete should be rich in cement.

Gravel. Thick beds of clean, dry gravel will safely carry loads of from 6 to 10 tons per sq ft.

Sand and Clay may give good bearing power if perfectly dry, or nearly so in the case of sand. But under ordinary conditions, it is difficult to prevent the entrance of water into such soils, and then the bearing power decreases very materially. If clay is on top of rock, a little moisture makes it impossible for foundation work, whereas the mixture of a small amount of clay in good sand or gravel will increase its bearing power.

Table II.—Safe Bearing Power of Soils by Baker (2)

Kind of Material	Safe Bearing Power in Tons per Square Foot	
	Minimum	Maximum
Rock, the hardest in thick layers in native bed	200	..
Rock, equal to best ashlar masonry	25	30
Rock, equal to best brick masonry	15	20
Rock, equal to poor brick masonry	5	10
Clay in thick beds always dry	6	8
Clay in thick beds moderately dry	4	6
Clay soft	1	2
Gravel and coarse sand well cemented	8	10
Sand, dry, compact and well cemented	4	6
Sand, clean, dry	2	4
Quicksand, alluvial soils, etc	0.5	1

18. Foundation Footings

The load to be carried by the foundation may be obtained by finding the weight of the entire structure to be supported and adding to that the extra pressure due to retained earth in retaining walls and bridge abutments; and the live loads and impact due to heavy traffic over bridge abutments and piers. This latter effect is very small and often negligible. Having found the load to be supported, the area of support is found by dividing this load by the safe bearing power of the soil. In order to obtain area enough at the bottom of the masonry to decrease the load on the soil to a safe value, and also to make the resultant pressure on the soil pass as nearly as possible thru the middle of the base, it is necessary to spread the footings. The amount of this spread is dependent upon the ability of the masonry to withstand the upward pressure of the soil. Having found the width of masonry in contact with the soil necessary to make the pressure fairly uniform thruout that width, and also to make the maximum unit pressure a safe one, the next step is to determine the decrease in width possible for the course of masonry on top of the bottom course, and so on up until the main part of the abutment or pier is reached. This offset as used for masonry footing courses is given in the following Table III by Baker (2), which gives a factor of safety of 10.

Table III.—Safe Offset for Masonry Footing Courses

Kind of Masonry	Offset in Terms of the Thickness of the Course for a Pressure in Tons per Square Foot on the Bottom of the Course of		
	0.5	1.0	2.0
North River bluestone	5.2	3.7	2.6
Granite	3.1	2.2	1.6
Limestone	2.7	1.9	1.4
Sandstone	2.7	1.9	1.4
Under burned building brick in 1 : 3 Portland, cement mortar at 76 days	1.9	1.4	0.9
Vitrified building brick in 1 : 3 Portland cement mortar at 76 days	4.9	3.1	2.2
1 : 2 : 4 Portland cement concrete at 1 month	1.2	0.9	0.6

Soils. Nearly all natural soils are compressible. Some not materially so, others considerably so; usually due to the presence of a comparatively small amount of water. In some cases greater bearing power may be obtained by simply going deeper. The weight of the soil causes it to be more compact at a greater depth. Another simple and very effective way of increasing the bearing power is by efficient drainage. Drain tile, placed a little lower than the bottom of a footing course, will materially increase the bearing power. But such drainage must have a proper outlet. If springs are encountered in making excavation, they should be led away by proper drainage. Efforts to plug them are liable to cause serious damage as they are often backed by a high head of water. Where soil contains considerable moisture, clean sand or gravel may be spread over the bottom of the excavation in layers of from 6 to 12 in and rammed into the soil. Small wood

piles may be driven into the soil. These are about 6 ft long and 6 to 8 in in diameter. Such piles are in no sense bearing piles, but merely compact the soil and act with it in forming a bed for the foundation. Additional bearing power may be obtained by withdrawing these wooden piles and filling the holes with dry sand, ramming the sand into place. This ramming increases the size of holes and further compacts the soil.

19. Pile Foundations

Where the soil is very wet and cannot be compressed so as to give sufficient bearing power, piles are commonly used. The most common piles are of wood. These should be fairly straight thruout their length and be not less than 7-in diameter at the tip. In hard driving, hard woods are best. In easy driving, soft woods are nearly as good. Woods that split readily do not make good piles for drop-hammer driving. There are two different kinds of pile-drivers. The drop-hammer driver has an iron hammer weighing from 1500 to 2000 lb falling freely between two vertical timber leaders 40 or 45 ft high. The hammer is raised by a rope which passes over a block at the top of a leader and winds up on a drum at the ground level. This driver gives heavy blows at comparatively long intervals. The steam hammer has a hammer weighing 2500 to 3000 lb driven thru a short blow by steam piston. The entire weight of the frame holding the steam cylinder and hammer rests on top of the pile and is guided by a leader as in a drop-hammer driver. The steam hammer gives very rapid blows, not allowing the earth to come to rest about the pile. It is a well authenticated fact that in most soils, the pile has greater bearing power some time after being driven than it has immediately after the last blow of hammer. The steam hammer takes advantage of the reverse of this condition.

In soils composed of silt, clay, fine sand or other fine materials, the sinking or driving of piles may be greatly assisted by use of a JET OF WATER applied at the tip of pile. This is carried by a hose or pipe down the side of a pile to the tip. It makes no apparent difference if the discharge is not under the center of the tip. The action is not to force the material out of place, but to flood the soil under pile so that the weight of the pile with the hammer on top will cause the pile to sink into it. Therefore, a large amount of water is required rather than high nozzle velocity.

In some cases, the upper portion of the soil may have no supporting power whatever, so that even if a pile penetrates hard pan, the upper part of the pile will act as a column fixed at the bottom. But in all ordinary cases, its resistance to buckling is greater than its bearing power under such conditions. Bearing power is dependent upon the bearing power of soil under the tip, usually small, plus friction between the sides of pile and the surrounding soil. Most commonly used formulas for bearing power are Engineering News Formulas, devised by Wellington: For drop-hammer driver, safe load in pounds $2\,wh/(s+1)$. For steam hammer driver, safe load in pounds $2\,wh/(s+0.1)$. In both formulas, w represents weight of hammer in pounds, h the fall of hammer in feet for last blow, and s the penetration of pile in inches under that blow. This last blow should be struck on solid wood and not on a broomed-out end. For large structures, or where the soil is very irregular, piles may be loaded to determine the bearing power. This is the only practical way to find the bearing power of concrete piles. Knowing the load to be carried, and the safe bearing power of pile, the number of piles may be determined by simple division. It is common to space piles on 3-ft centers in staggered rows.

Concrete Piles. Except for temporary structures, wood piles should not be used except where they will always be wet, unless they are thoroly creosoted. Recent years has seen the introduction to a large extent of concrete piles. These not only withstand ordinary decay, but are also unaffected by the various wood destroying animals in southern waters. The Raymond concrete pile is made by driving into place a tapering shell of sheet iron covering a collapsible core. These may be had of almost any ordinary size. After driving, the core is collapsed and withdrawn. The shell is filled with concrete. The Standard Simplex pile is made by first driving a cast iron cylinder, to the bottom end of which is loosely fastened a blunt pointed cast iron cone. After driving, concrete is placed to a depth of 2 or 3 ft and the cylinder is raised leaving the point in place. The concrete is in contact with soil, and by tamping, further compression of the soil is obtained. This process is repeated until the top of the pile is reached. Both Raymond and Simplex piles may be reinforced. The use of iron and steel piles has been almost entirely discontinued by the introduction of concrete piles.

Sheet Piling is used for coffer-dams where it is necessary to work several feet below the normal water level. Wood sheet piling is made by driving 2 by 6 to 10 in planks edge to edge. These should be carefully guided in order to keep the joints tight. Waling-pieces are used to help guide the piling. Also the tip to one edge of plank is sharpened. Two or three thicknesses of planks will give the best results, each thickness breaking joints with those already driven.

Steel Sheet Piling will withstand much greater pressures. They are driven in just the same way as the plank, except that they interlock on their edges, and thus assure practically tight joints. Joints may be made tight by driving wooden strips into the interlock. These swell and tighten the joints. While steel piling has a higher initial cost, it may easily be withdrawn and used again, whereas the plank is largely destroyed.

If bed rock can be reached without serious difficulties, footing courses for bridge abutments and piers should be placed on such rock. This does away for all time with any trouble from scour during spring floods. Even with sand and gravel, the footings should be carried well down below the top surface unless piles are used. And in all cases, other than rock bed, large stone or rip-rap should be piled around the bottom of the abutment or pier in sufficient quantity to avoid all danger due to scour.

See (2), (9) and (12b).

20. Coffer-Dams

The most common method of placing footings and foundations under water is to build some form of coffer-dam around the site and pump out the water. If the water is not over 3 or 4 ft deep, and there is practically no current, the coffer-dam may be built of material excavated from the site of foundation. If there is a current, washing away of such a wall may be prevented by surrounding it with bags filled with gravel or with gravel and clay. If the current is very considerable, build the entire wall of bags filled with gravel and clay. For depths up to 6 or 8 ft, plank sheet piling may be used without a puddle. A puddle-wall coffer-dam is built by driving two rows of sheet piling all around the site of foundation. The distance between the two rows should not be less than ¼ the depth below the water level. This space is always filled with gravel, gravel and clay, or gravel and loam. Gravel should always be present, as leaks thru the

puddle will often stop themselves by gravel filling the leak. Clay or loam will arch over such a leak and not fill it. For depths up to about 10 ft, the rows of sheet piling may be braced by 8 by 8 in timbers forming a horizontal frame all about the inside of the piling. These timbers are called wales. For greater depths, it may be necessary to drive ordinary wood piles from 6 to 10 ft apart and brace the sheet piling to these. See (9) and (12b).

21. Pumps

The use of coffer-dams involves the use of some kind of pump to keep the site of the foundation free from water. If the water is shallow and the dam is tight, the water may be removed by an ordinary plunger pump worked by hand. Such a pump is, however, seldom sufficient. The diaphragm pump consists of a short cast iron cylinder with a flexible rubber diaphragm horizontally across at the mid-height of the cylinder. The pump handle, fastened to the middle of the diaphragm, gives the piston action by the rise and fall of the diaphragm, in center of which is the valve. It is operated by hand or by gasoline engine and has a capacity of 25 to 100 gal per min.

Steam Siphon Pumps operate by the creation of a partial vacuum in the intake pipe by the injection of steam within or near the entrance to the discharge pipe. Of the several siphon pumps on the market, the most common is the pulsometer. If water in large quantities must be handled, the centrifugal pump should be used. This is a siphon pump where the vacuum is created by a fan revolving in a cylindrical case. The intake is at the center of the cylinder and the discharge is at the circumference. The amount of water handled is dependent upon the speed of the fan which may be run at from 400 to 700 rev per min. The most common sizes have discharge pipes of 6, 8 and 10 in and the largest at high speed having a capacity of 14 000 gal per min. See (9) and (12b). Another important advantage of a centrifugal pump is that the only valve is the flap valve at the foot of the intake. When in use, this is constantly open and permits the free passage thruout the pump of stones of considerable size.

GUARD RAILS

22. Wooden Guard Rails

Along both sides of fills of any considerable depth, there should be built guard rails or fences. Wooden fences are built of cedar, white oak or chestnut posts 6 in in diameter. These are 6 ft 6 in, Massachusetts standard, or 7 ft, Connecticut standard, in length, placed 3 ft 6 in above the ground. The top of the post is fish-tailed in the line of the fence and the top rail is made of 4 by 4 in timber set into fish-tail so that the diagonals of cross-section of timber are horizontal and vertical. Or the top of post may be sloped about 30°, and 2 by 6-in planks spiked across the tops. Posts are set 8 ft apart, and rails should be 16 ft in length. Another rail of 2 by 6-in plank should be fastened to highway side of the posts so that the top edge of this rail is about 1 ft 6 in below the top of the post. All joints in the top rail should be covered with a sheet of zinc thoroly nailed down to prevent water from getting into the joint. The entire fence should be painted with two coats of white lead and oil, making them visible at night. Such guard rails cost from 25 to 40 cents per lin ft.

23. Iron Pipe Railing

Across culverts or where the road is retained by masonry walls, pipe fences may be used. The Massachusetts standard iron pipe fence requires the posts to be of 2-in pipe and rails to be of 1½-in pipe. There are 3 rails spaced 13 in center to center, the center of bottom rail being 16 in above the ground. The Connecticut standard requires posts to be of 3-in pipe and rails to be of 2-in pipe. Two rails 15 in center to center, the center of bottom rail being 15 in above ground. Posts are set not more than 8 ft center to center and are sunk 10 to 12 in into the masonry thru cast iron flanges, which are 6 in in diameter for 2-in pipe and 7 in in diameter for 3-in pipe. The flanges are bolted to the concrete by four ⅝-in or ¾-in bolts. The fences should be painted with two coats of white lead paint.

24. Cement-Concrete Guard Rails

Concrete. Wherever there is slightest danger from brush fires, or where timber is more expensive than concrete materials, concrete and wire fences or concrete fences may be built. Concrete posts should be about 7 ft long with 3 ft 6 in in the ground. They are 5 in square at top end and 6 in square at bottom end. For wire fences, place ½-in round rods, greased, in the forms in which the posts are cast, in such a way that the rods may be withdrawn leaving holes for the wire strands to pass thru. Or take pieces of No. 12 copper wire, bend in the middle and insert them in the post forms so that about 2 in of the free ends will be outside the face of the posts to fasten the wire fencing to the posts. Cost will vary from 10 to 25 cents per lin ft.

Concrete guard rails may be built of concrete rails set on top of concrete posts. The rails are built with a rectangular trough section fitted with cross diaphragms connecting the side and top. The rails are generally reinforced and are set about 3 ft 2 in above the ground. The cost of concrete guard rails is estimated to be about 50 cents per lin ft.

Concrete Parapet Walls in place of pipe rail fences may be built 2 ft 6 in high and 8 in thick with panels 1 ft 2 in high and not over 7 ft 4 in in length for 8 ft center to center of panels, sunk 1 in deep into each side of the wall, making the wall 6 in thick at panels, and leaving 8 in of thickness around the panels. This wall should be reinforced by 3-in 10-gauge expanded metal weighing 0.9 lb per sq ft, placed in the middle of the thickness of the wall running its entire length, and extending from the bottom of the wall to within 3 in of the top. Also in the middle of the thickness of the wall and wired to expanded metal, should be placed ¾-in twisted square rods extending vertically from 3 in below top of wall to 20 in into concrete below parapet wall. These should be spaced not over 4 ft center to center, that is, two to every panel length; 1½ to 2 in inside the two top corners of the wall should be placed ⅜-in twisted square rods running horizontally the entire length of wall. At each end of wall and cast as an integral part of the wall, place concrete post 12 in square and 2 ft 8 in high, having the corners chamferred to match the panelling of the wall. The top of post should be a square pyramid, 1 in high. Place one of the ¾-in vertical rods in the middle of the post and continue the expanded metal thru 10 in of the post, that is, within 2 in of the end of concrete.

PRESERVATION OF MATERIALS USED IN HIGHWAY STRUCTURES

BY

HENRY A. GARDNER

ASSISTANT DIRECTOR, THE INSTITUTE OF INDUSTRIAL RESEARCH, WASHINGTON, D. C.

CORROSION AND PRESERVATION OF IRON AND STEEL

DECAY AND PRESERVATION OF WOOD AND MASONRY

CORROSION AND PRESERVATION OF IRON AND STEEL

1. Corrosion of Metal

Causes of Corrosion. Iron corrosion is generally due to self-electrolysis which is distinct from the type of external corrosion caused by escaped currents from high potential electric lighting or power circuits. Iron always contains impurities such as carbon and manganese which, when segregated, in the presence of moisture, are electrically opposed to iron. These impurities are generally of an electro-negative nature and thus force the electro-positive iron into solution. The air present oxidizes the iron in solution and precipitates it out as rust. The water thus freed from the iron oxide again attacks the metal, serving as an electrolyte for the currents that flow from different areas of the surface. Under favorable circumstances, this reaction may proceed until the metal is entirely transformed into rust. This would indicate that the approach of iron or steel to chemical purity will lead to added resistance to corrosion. The presence of impurities invites segregation which causes surface differences of potential and stimulates electrolytic action. Freedom from gases is also an important factor in the manufacture of corrosion-resisting metal. Scratches, pitholes or abrasions on steel become centers of corrosion, as they are electro-positive to surrounding areas. In assembling metal parts in structural work, metals containing different percentages of carbon or other impurities are apt to set up corrosion at points where they touch, the electro-positive metal being rapidly destroyed. It is therefore advisable to have all rivets of the same composition as the plates which they fasten together.

Acids present in water stimulate electrolytic action. Contact with carbonaceous substances also stimulates corrosion, as such substances tend to make iron more electro-positive, and thus increases the differences of potential. Unequal strains or stresses on the surface of the metal also have a corrosive tendency.

Effect of Water and Impurities in Water. The presence of carbonic and sulphuric acid in the air in industrial communities causes considerable more corrosion at such points. These impurities are absorbed from the air by rain water which may fall upon iron structures. Waters containing most salts or acids increase the electrical conductivity of the solution and therefore stimulate the galvanic action which is responsible for corrosion. Salt water stimulates corrosion rapidly on account of its conductivity. Mine waters stimulate corrosion on account of the presence of sulphuric acid. Strongly alkaline water actually inhibits corrosion, as it tends to make the surface of the metal passive to electrolysis. Very dilute alkaline water, however, causes a tendency to pit. The presence of dissolved oxygen in water causes rapid corrosion. If water, which is to be used for boiler purposes, is first freed from its oxygen content, much less corrosion of the tubes will occur. The oxygen in sewage-laden waters has been used up in oxidizing the organic matters present. For this reason, sewage water does not exert as corrosive an action upon metal as ordinary fresh water. Iron assumes a passive state, in which it will not rust, after it has been dipped into a strong solution of certain oxidizing agents, such as chromic acid, potassium bichromate or strong nitric acid. This passivity of surface remains for some time, even after removal from the oxidizing reagents. Bichromate of potash is probably the most efficient inhibitor. Two pounds of the salt dissolved in 3000 gal of water furnishes a solution which will keep steel bright when immersed therein. The surface of the steel is rendered passive and does not rust. Immersion of steel in a 5% solution of potassium bichromate, subsequently washing off the solution, produces a passivity which resists corrosion in the air for some time. In rapidly moving waters highly charged with oxygen, the corrosion of iron would not be as great as in still waters similarly charged. This is especially true of pipe lines. It is due to the fact that the constant swirl of the waters prevents differences of potential on various surfaces from being permanently established, as would be the case if the water was quiet.

2. Preservation of Metal

Zinc Coatings. Zinc is a highly electro-positive metal and is best suited to use as a metal protective coating on iron. On account of its electro-positive nature, it goes into solution in water, the iron being electro-negative in this reaction and thus protected from corrosion. There are three methods of applying zinc coatings to iron. The HOT DIP METHOD is carried out by dipping or drawing the iron thru a tank of melted spelter, subsequently drawing thru asbestos wipers or putting thru rolls to remove the excess zinc. The iron is first pickled in acid to remove the scale from the surface. The presence of any considerable percentage of arsenic in the zinc produces an inferior coating. Alloys of zinc and iron, when formed in the bath and coated upon metal, reduce the electro-positive nature of the coating and thus reduce its efficiency. In the ELECTROLYTIC METHOD OF GALVANIZING, the zinc is deposited in a pure condition by electrolysis of a zinc solution. The method, however, requires consid-

erable time and consumes much current. Heavy smooth coatings cannot always be obtained. The VAPOR PROCESS of depositing zinc is known as SHERARDIZING. The articles to be coated, generally small articles, such as hardware, are placed in an iron drum, in contact with zinc dust, and a temperature of 316° C (600° F) reached. In one process the articles are placed in a rotating cage in contact with the gas from a reservoir of molten zinc. In vapor processes very even coatings are obtained, the inner part of which is generally alloyed with the iron. Articles vapor-galvanized have a surface which takes paint much better than the smooth spangled surface produced by hot galvanizing.

Tin Plate. Tin is extremely resistant to corrosion and is therefore used in a large way for coating iron to form tin plate, especially for roofing purposes. It is difficult to apply a coating of tin to a metal so that pinholes are not left; in fact, most all tin plate contains pinholes at various spots, the uncoated iron upon exposure going into solution and forming rust spots. These are easily detected on new tin by floating over the surface of the plate a solution of hot gelatine containing a small amount of potassium ferri-cyanide. The gelatine hardens upon cooling. The pinholes will be shown by a brilliant color which indicates reaction between the uncoated iron and the potassium ferri-cyanide, with the formation of Prussian blue. Heavily coated tin plate will show very few, if any, spots.

Copper is used to a considerable extent for the coating of metal; copper-coated wire and copper-clad steel being especially valuable for some purposes. In case of abrasion, however, rapid corrosion is apt to occur, since iron is strongly electro-positive to copper. This corrosion, however, proceeds for a time and then stops, a thin film of copper compounds forming as a preservative coating over the iron.

Lead is used to a considerable extent for coating iron (terne plate), and for some purposes is very useful. It is not as durable as well galvanized or heavily coated tin plate.

Special Protective Treatments. There are many other methods of treating iron, among which may be mentioned the BOWER-BARFF PROCESS of producing a surface of black magnetic oxide by heating the metal to 815° C (1500° F) in a chamber to which is admitted superheated steam or producer gas rich in carbon monoxide, black magnetic oxide being thus formed upon the surface. This is quite extensively used for small articles, such as iron grilling, builders' hardware, stove pipes, etc. The cost of the treatment ranges from $5 to $20 a ton. Articles, thus coated, are resistant to corrosion, but when they are scratched or abraded rapid corrosion will occur, since the coating is electro-negative. Many articles made of iron which cannot be subjected to the various treatments previously mentioned are sometimes made of alloys containing chromium, vanadium and other metals. These are resistant to corrosion but are expensive. Immersion of iron in fused sodium nitrate and other salts gives surface oxide coatings which are more or less resistant for a time to corrosive tendencies but are less effective than the protection given by paint.

3. Paints for Iron and Steel

Paint for Metal. In the design of protective coatings for metal surfaces, the modern practice has been to apply the results of recent studies into the causes of corrosion. Since in these studies it was found that substances of a basic nature or materials which contain soluble chromates prevent the

corrosion of iron, pigments of a basic nature or pigments which contain the chromate radical have been widely adopted for use in paints for the protection of metal from corrosion. In exposure tests at Atlantic City to determine the durability of various pigments in oil as protectives of metal surfaces, over 300 large steel test panels were exposed in 1908. See Proc. Am. Soc. Test. Mat., 1910–1917. These were all given three coats of paint made of various materials. Careful inspections were made every year, the rating of 10 indicating perfect protection and 0 indicating total failure. The ten panels receiving the highest ratings during 3 years of inspection are given herewith:

Ten Highest Ratings

1912		1913		1914	
Pigment	Rating	Pigment	Rating	Pigment	Rating
American vermilion	9.9	American vermilion	9.8	American vermilion	7.5
Zinc-and-lead chromate	9.2	Zinc-and-lead chromate	8.3	Sublimed blue lead	6.0
Sublimed blue lead	9.0	Zinc chromate	8.0	Carbon black	5.0
Zinc chromate	8.8	Willow charcoal	7.9	Chrome green	5.0
Willow charcoal	8.6	Zinc-and-barium chromate	7.8	Willow charcoal	4.5
Chrome green	8.6	Magnetic black oxide	7.8	Red lead	4.0
Magnetic black oxide	8.6	Chrome green	7.6	Natural graphite	4.0
Zinc-and-barium chromate	8.5	Sublimed blue lead	7.2	Zinc chromate	4.0
Sublimed white lead	8.1	Carbon black	6.8	Zinc-and-lead chromate	4.0
Red lead	8.1	Prussian blue (water stimulative)	6.7	Magnetic black oxide	4.0

Unfortunately, chromate pigments are expensive and are therefore used only in small percentages in metallic paints, generally in combination with iron oxides. The sublimed lead pigments, the iron oxide pigments and red lead are reasonable in price and have therefore been adopted as the bases of many protective coatings.

Inspection of Metal Surfaces. In inspecting painted metal to determine the durability of various paints, the following should be noted. Chalking of paint is shown when the paint is rubbed with the hand or a black cloth. This indicates destruction of the oil. Moderate chalking is not detrimental. Checking or crazing of surface is shown by paints which are not elastic and which become brittle upon exposure. Elasticity of film can be determined by scraping the paint with a knife. Brittle coatings crumble; elastic paints produce long elastic films. The underlying metal should be examined with a magnifying glass for evidences of rust. Hardness of paint and resistance to moisture are shown by drawing a line with a fountain pen upon the surface. If the ink does not spread, the surface is hard and does not absorb moisture.

Painting Galvanized Iron. Galvanized iron is widely used for siding, roofing, railings, cornice work, drain pipes, fence wire, etc. On account of the smooth, spangled surface, ordinary paints will peel after a short period of time. This may be overcome by first treating the metal before painting with a solution made by dissolving 4 oz of copper acetate, copper sulphate or copper chloride in 1 gal of water. The application of this solution produces a rough dark surface. A few hours after the applica-

tion, the surface may be lightly brushed and then painted with a rust inhibitive paint. The paint will firmly adhere to such a surface.

Painting Tinned Surfaces. The rapid corrosion of tin plate points to the necessity of painting tin roofs a day or so after placement. The palm oil or other grease upon the surface may be removed by wiping with a cloth saturated with benzine. The paint may then be applied. Iron oxide paints containing 10% of zinc chromate have given excellent results for this purpose.

Painted Culverts. Culverts, plain or corrugated, are usually galvanized. If the coating is heavy, the corrosion resistance is usually excellent except in strongly alkaline soil that has a solvent effect upon zinc. Black iron culverts that have been painted may replace galvanized culverts for some purposes. The black culvert segments should be coated at the factory with a rust inhibitive priming coat of paint made of red lead, blue lead, chromated or litharged iron oxide, etc. After forming, the culverts should be dipped at the fabricating shop in a black, water-resisting, liquid bituminous paint made of asphalt or blown petroleum residue. Such paints dry rapidly and do not become soft during shipment as would be the case if the culverts were dipped in hot asphalt or tar. Culverts treated in the manner outlined above should withstand corrosion for many years, if the base metal is corrosion resistant.

Bituminous Paints. Tar and asphaltic paints have come into wide use for coatings upon cast iron or riveted steel water carriers. Some of these are made by blending asphalt with coal tar pitch, linseed oil, resinous varnishes and similar ingredients, altho the modern practice is to use heavy petroleum residue, sometimes fluxed with gilsonite. This is usually heated to 150° C (302° F) or over in order to bring it to a molten condition, the heated pipes being plunged therein and removed. The adhered coating becomes hard in the air in a short period of time. Subsequent baking produces a more resistant film.

Coal tar paints for brushing purposes should be made from refined tar that has been freed from ammonia and water, which cause saponification and non-adherence. The presence of much naphthalene or free carbon is detrimental to such paints and is apt to cause crazing and early disintegration. For the preparation of coal tar paint, refined tar should be heated to 120° C (248° F) until the water is evaporated. Ten percent of quicklime may then be added to neutralize the free acids. A small quantity of Portland cement may also be added, if desired. This mixture may be applied hot. When making a thinner paint to be applied with a brush, there may be added to the heated coal tar 5% of quicklime, 5% of red lead and 20% percent of gloss oil made by dissolving rosin in an equal part of benzine. This paint dries rapidly to a hard film having a high gloss. Coal tar paints are not very serviceable when exposed to the sun, since alligatoring or checking takes place, the action of the sun causing disintegration of the tar and the formation of free carbon. This is partially overcome by the addition of Chinese wood oil and asbestine to a coal tar paint. These paints have proved very serviceable when applied to metal that is to come in contact with acid fumes, such as pipe lines or tanks in or near acid factories.

Tunnel Work. Iron in tunnel work may be protected from corrosion by the application of a prime coating of red lead or other inhibitive paint, subsequently applying an asphaltic or coal tar paint, such as those outlined above. An asphaltic paint which gives good results for this purpose may

be prepared from a heavy blown petroleum residue fluxed with gilsonite. This is dissolved in benzol, turpentine or a mixture of these solvents with petroleum distillates.

Marine Paints. Metal that is to be exposed in salt water or marshy land is subject to rapid corrosion and incrustation with marine growths. It is advisable in some cases to apply to such metal paint coatings of an anti-fouling type, which contain soaps of copper or other poisonous compounds, or which contain oxide of mercury or bichloride of mercury. Such paints are usually made upon a shellac-alcohol base, zinc and iron oxides constituting the major part of the pigment portion.

Tank and Steel Timber Paints. Iron water-tanks along roadways will rapidly corrode unless painted both on the inside and outside. A very satisfactory, hard drying paint for this purpose may be prepared by adding 2 lb of litharge to a ready mixed red lead paint. A water-resisting bituminous paint should be applied as a top-coater. Steel mine timbers which are subjected to the effect of sulphur water and gases in mines may be protected with the same paints.

General Structural Steel. Bridges, general structural steel work of all kinds, lamp-posts, letter boxes, ornamental ironwork, etc may be efficiently preserved from corrosion by the application of prepared rust inhibitive paints such as those shown below.

Red Lead Paints. When red lead is ground in oil to a stiff paste, 100 lb of the paste may be reduced with 2 gal of oil and 2 pints of turpentine drier. This will furnish a little over 4 gal of paint, containing about 33 lb dry red lead per gallon. The spreading rate of this paint will be about 400 to 500 ft per gal. The cost of the paint will be about $2.50 per gal. Red lead paste is usually made of red lead that does not contain any free litharge. Consequently, the protective quality of the red lead is reduced. The best practice is either to purchase a ready mixed red lead paint or to use pure dry red lead purchased on the following specifications, mixing the paint on the job:

SPECIFICATIONS:

1. The dry pigment to be of the best quality, free from all adulterants and not to contain less than 85% nor more than 90% Pb_3O_4, the remainder being practically pure lead monoxide, PbO.

2. It shall contain not more than 0.1% of metallic lead nor more than 0.1% of alkali figured as Na_2O.

3. It shall be of such fineness that not more than 0.5% remains after washing with water thru a No. 21 silk bolting-cloth sieve.

FORMULA FOR MIXING DRY RED LEAD PAINT:

Specification red lead	26 lb
Raw linseed oil	28 gills
Turpentine	4 gills

This will yield about 1²/₅ gal of paint costing about $1.75 per gal. For tinting this paint to a chocolate color for final coat work, add 4 oz of lampblack in oil to 1 gal of paint. This paint may be used upon all structural work.

Blue Lead Paints. Blue lead paints may be purchased in prepared form on the following formula which can be used for the priming coat on all types of structural work:

Sublimed blue lead	64 lb
Linseed oil	32 lb
Turpentine drier	2 lb

If desired, blue lead may be purchased ground in oil in the proportion of 90 parts of pigment to 10 parts of oil. For first coat work 100 parts of the paste should be thinned with 4½ gal of oil and 1 quart of turpentine. For second and third coat work, 100 parts of paste may be thinned with 5 gal of oil and 1 pint of drier. The cost of blue lead paints will average about $1.50 per gal. The spreading rate will average about 900 ft per gal.

Iron Oxide Paints. Rust inhibitive paints made upon an iron oxide base and containing from 10 to 15% of zinc chromate, red lead, zinc oxide and similar inhibitive pigments, come in prepared form ready for use. The cost is usually about $1.50 per gal and the spreading rate about 900 ft per gal. These paints are especially suited for application to tin roofs and metal siding or for general structural purposes.

Black Paints. Carbon black and graphite form the pigment base for many prepared protective paints. Litharge, red lead, silica and other pigments are sometimes added. These paints should be used as top-coaters over a thoroly inhibitive priming coat of paint. Black iron oxide is coming into use as a permanent black protective coating. In practice it has given excellent service.

Estimating Areas and Paints for Steel Structures. Chapman (9) gives the following:

"The surface area of a steel structure may be calculated by use of the following formulas in connection with the material bills giving the tonnage of the various shapes:

"Let S = square feet of surface per ton of metal, and w = weight of shape per running foot, pounds. Then, for

"I-beams: $S = (56\,800h + 54\,800)/w$; where h = depth of beam, inches.

"Channels: $S = (434b + 500)/w$, where b = width of channel, inches.

"Angles (equal-leg): $S = (660b - 21)/w$, where b = width of each leg, inches.

"Angles (unequal-leg): $S = 3220b/w$, where b = sum of widths of both legs, inches.

"Z-bars: $S = (52h + 1090)/w$, where h = depth of web (out to out), inches.

"Plates (both sides): $S = 100/t$, where t = thickness, inches."

The spreading rate of metal paints will average from 500 to 1000 ft per gal, according to the pigments used and condition of surface. Red lead paints generally average 700 ft; iron oxide paints, prepared rust inhibitive paints and blue lead paints, 900 ft per gal.

4. Prevention of Electrolysis in Concrete Structures

Paints to Prevent Electrolysis. Rapid corrosion takes place when an electric current is passed thru an iron anode immersed in an electrolyte, such, for instance, as salt water. When damp cement contains an embedded iron anode the cement acts as an electrolyte, and the same rusting action takes place, regardless of the fact that concrete contains sufficient lime to inhibit corrosion when no electrical currents are present. With the electrolytic change of metal into oxide comes an increase in volume of the products of reaction, and there is developed an enormous expansive force of mechanical pressure, which is sufficient to crack the strongest forms of concrete.

Sources of Currents. Corrosion may therefore be expected, with its attendant results, when sufficiently high voltage direct currents enter the

iron of a concrete structure, either thru contact with conductors of light and power circuits, contact with water or gas pipes carrying direct currents from grounded power lines, thru defective insulation of electrical wiring, or from similar sources. That the damage is greatest to new structures is due to the fact that the concrete is then damp and a better electrolyte than when it becomes dry from age. Much of this damage may be prevented by the adoption of suitable forms of foundation waterproofing, exterior insulating joints for pipe lines, isolation of lead-covered cables entering buildings, and other insulating devices. Of equal importance, however, should be the safeguarding of the metal with suitable insulating and bonding paints before it is embedded in cement.

Method of Making Good Bonding Surfaces. In making up specimens for test, the objection to using paints which dry upon metal to a gloss surface and which prevent proper bonding of the cement might be overcome by applying to the painted surface, while it is still tacky (not dry), sharp particles of sand or similar material. Emery powder, abrasive, and fine quartz sand have been used. When allowed to drain upon a painted rod, the particles become attached to the paint and dry with it, forming a rough surface resembling coarse sandpaper. After thoroly drying, the particles are solidly embedded in the paint, which thus presents a dull rather than a gloss film. Fine, clean, white sand was found most useful.

Tests for Bonding Surfaces. In one series of tests the specimens were made by embedding in concrete cylinders painted anodes ¾ in in diameter and 12 in in length. The rods, previous to painting, were thoroly cleaned from scale and rust. They were painted with two coats of paint. The rods were placed in 3½ in by 8 in molds, in an upright position, and a mixture of one part of Portland cement and two parts of sand was poured around the rods and tamped into place. The specimens for this series were very carefully prepared. After setting for two days, the molds were removed from the pieces, which were then aged for a month. They were then placed in water for 24 hr, and the next day were placed in individual earthenware jars containing sheet-iron cathodes, coiled so as to surround, but not touch, the cylinders. The jars were filled with sufficient water to cover the cylinders up to within 1 in of their top surfaces. The specimens were connected up in parallel and in series with resistance to reduce the voltage from 110 to 30 volts direct current. The tests were continued for 240 hr at 30 volts. The voltage was then increased to 55 and continued for 60 hr, at which time the tests were discontinued.

Test of Bonding Value. In order to determine the comparative bonding strength shown by the various painted rods with the surrounding concrete, a series of test specimens was prepared, the rods being placed flush with the bottom surface of each cylinder. After aging for three weeks, the specimens were tested in a Riehlé testing machine, being placed on an iron slab drilled thru the center with a 1-in hole to allow an entrance space for the rod in the test specimen when subjected to pressure. Each test specimen was placed in such a position that the lower end of the contained iron anode would be in alignment with the hole below. Pressure was applied until the painted iron rod was pushed away from the surrounding cement and the bond destroyed.

Observations on Results. In the test specimens where cracking had occurred the anodes showed considerable rust, the paint coatings originally applied having been destroyed. On the cathodes the paint coatings were still intact, altho some had apparently been affected by the moisture and the hydrated lime on the wet concrete, chalky surfaces being shown. Wherever there were small voids in the concrete, at or around the painted anodes, corrosion was most severe, and at such places pitting was shown. The protective coatings upon the anode and cathode bars embedded in the concrete cylinders which did not crack and which carried but little current were later found to be in a very good state of preservation.

Incidental Reactions. The breaking down of a film upon the embedded iron rods was always recorded by a sharp rise in the amperage, due to the decreased resistance offered to the flow of the current between the electrodes. The hydrogen gas formed

seemed to have a reducing or softening action upon some of the oxidized coatings, and carried to the surfaces of the cylinders considerable quantities of soft oily products, which deposited around the anodes and later hardened in contact with the air. Iron oxide was also carried to the top surfaces of some of the specimens by the action of the gas and water, and was there deposited as a dark brown stain.

Value of Well Dried and Saturated Films. Paint films that have been baked, on account of their fully saturated condition, do not act as depolarizers. It would obviously be impractical to bake paint coatings upon most forms of reinforcing metal, but quite thoroly oxidized coatings, which would probable have but slight depolarizing action, would result by allowing a period of 60 days for the drying of oil paints after application to the metal and previous to immersion in the cement. It is, moreover, possible to apply coatings which do not depend entirely upon oxygen absorption for their hardening and which contain ingredients of a fairly saturated nature. Among these could be mentioned such coatings as are composed of rosins dissolved in volatile solvents, as well as some special types of oil coatings.

Use of Pigments. The addition of a pigment to an oil usually increases the moisture resistance and makes a more impermeable film.

Conclusions. The corrosion of metal embedded in concrete structures by stray currents of high voltage is often productive of serious effects. The use of properly made paints upon such metal constitutes a safeguard that should not be neglected by the engineer. Such paints may be prepared from the following substances. The vehicle should contain: Boiled or bodied oils or products which dry to a fairly saturated film; oils which dry by semi-polymerization rather than oxidation; oils which dry to a flat rather than a highly glossy surface. The solid portion should contain a percentage of: Pigments which are coarse and which therefore tend to form films having a rough surface; pigments which are inert and which do not act as conductors of electricity; pigments which are either basic or of the chromate type. The painted metal should be sanded if possible.

DECAY AND PRESERVATION OF WOOD AND MASONRY

5. Decay, and Preservative Treatments of Wood

Causes of Wood Decay. The decay of wood is generally due to low forms of plant life called fungi which produce micelia (roots) or contain spores which are blown about by the wind. These fungi have the property of secreting chemicals which dissolve wood fiber, the wood thus serving as a food for the fungi. The chemicals evolved are termed enzymes or ferments. Various forms of insect life have a destructive action upon wood. Some of these are called borers, timber worms, etc. They bore channels into which water enters, thus destroying the wood. Mechanical abrasion is another cause of wood decay. Alkaline soils may also have some effect in the destruction of wood, but fungous growths are mainly responsible.

Effect of Seasoning. Seasoning of timber tends to prevent decay, increases durability and strength, prevents shrinking and cracking, reduces weight, and conditions the fiber for the injection of preservatives. Open air seasoning, hot air seasoning and seasoning in steam and oil are used for this purpose.

Preservative Treatments. Linseed oil paint is probably the most important wood preservative and should be used wherever possible. The film produced by the dried paint effectively excludes fungi and other causes

of decay, and, at the same time, beautifies the structure. For certain purposes, preservation with creosote and substances of a high fungicidal value is necessary. Various treatments are used for this purpose, among which is the so-called brush treatment, the preservative being applied with a brush to dry wood after air seasoning. Good results are obtained with creosote that has been heated to 180° C (356° F) before application. The preservative will penetrate about ¼ in. This treatment is cheap and convenient. By dipping the wood into the preservative, more effective results are obtained. This treatment requires a tank and is well adapted to such products as shingles, posts, poles, etc. Impregnation processes give the best results, as the preservatives are forced deeply into the wood. Impregnation processes are more expensive, however, and require considerable apparatus. They include various non-pressure, pressure and vacuum processes. The impregnation is usually deep and effective. In the open tank process, lumber is placed in a bath of hot oil in order to drive out the air, sap and water. The wood is then placed in a cold solution of preservative which is drawn in by contraction. Pressure processes, in which the timber is placed in tanks or wells containing preservatives under pressure, include the Bethell, Buehler, A. C. W., Lowry, Burnett, etc. The life of piling, road-ties, poles, cross-arms, etc, is increased greatly by these treatments. In the kyanizing process, timber is kept submerged several days in a solution of bichloride of mercury. This is not a good treatment for timber that is to be kept in a wet place where the bichloride salt would leach out.

Materials Used for Preservatives. Of the various water-soluble preservatives used, copper sulphate, mercuric chloride, zinc chloride and sodium fluoride have given the best results. Sodium fluoride has an extremely high fungicidal value. Zinc chloride is low in cost. Creosote is a very important preservative on account of its phenol content, this substance having a high antiseptic value. Various forms of coal tar creosote, water-gas creosote, wood tar creosote, mixed creosotes, etc, are used. Their value depends upon their toxicity.

For treating poles and posts, the brush treatment is effective after proper seasoning of the wood. The life of the wood may be increased five years by this method. Treatment of the ends, to a height of 20 in above ground, in a tank for five days is very effective. Coal tar creosote is often used for this purpose. Zinc chloride (5% solution hot) or other antiseptic salts may be used. Application of an oil paint will prevent leaching out of the preservative. The cost of brush treatment of 6-in posts with coal tar creosote, or impregnation with zinc chloride, varies from 3 to 6 cents. A simple form of treating tank may be made from a 100-gal iron drum mounted on a plain brick foundation which can be used as a fire-box. The preservative is placed in the tank and heated, the posts subsequently being placed in for treatment.

Painting Wood That Is to Be Preserved. Wood may be first brush-treated with zinc chloride, mercuric chloride, sodium fluoride or bichloride of mercury. Linseed oil paints may then be applied. This process is especially valuable for treatment of wood in greenhouses, dye houses, etc, where there is much moisture and heat. For rendering wood fire-retardant, it may be coated with a chemical like sodium silicate which, when heated, will fuse and retard combustion, or it may be impregnated with ammonium salts which, when heated, will liberate non-combustible gases. Sodium bicarbonate, oxalic acid, borax, ammonium chloride and ammonium

fluoride are also valuable fire-retarding salts for impregnation purposes. Paints should be applied after impregnation, in order to prevent leaching out of the salts.

6. Paints for Wooden Surfaces

Paints. The pigments which are used in paints for wooden surfaces are those opaque white pigments, such as corroded white lead (basic carbonate-white lead), sublimed white lead (basic sulphate-white lead), zinc white (zinc oxide), and leaded zinc (mixture of lead sulphate and zinc oxide). The so-called white, inert, crystalline pigments include barytes (barium sulphate), asbestine (magnesium silicate), silex (silica), china clay (aluminum silicate), whiting (calcium carbonate), gypsum (calcium sulphate). White lead, when used alone, will chalk rapidly and will often check deeply. When zinc oxide is used alone, scaling and cracking may be shown. When white lead and zinc oxide are combined, the defects of each are overcome and an excellent paint is obtained. These mixtures of lead and zinc pigments are sometimes combined with small percentages of the inert crystalline pigments mentioned above. These combinations are finely ground in pure linseed oil by machine and thinned down to painting consistency with turpentine and drier. They are sometimes tinted with color pigments, such as Prussian blue, lead chromate, lampblack, umber, sienna, ochre, etc. A good specification upon which to purchase prepared paints of the above type is given herewith.

Specifications for Prepared Paints for Wooden Surfaces adopted in 1915 by United States War Department.

The paint must be furnished in prepared form, ready for application. White paint must contain not less than 65% nor more than 70% of pigments, the balance to be liquids. The liquids shall consist of pure raw linseed oil containing a total of not over 10% of turpentine and turpentine drier. The pigment portion of the paint shall consist of white lead (basic carbonate or basic sulphate) and zinc oxide. There shall not be less than 25% nor more than 50% by weight of zinc oxide. Paints of this composition containing, in addition, not over 15% by weight in the pigment portion of such white pigments as barytes, china clay, whiting, asbestine and silica will be accepted under these specifications.

Oils Used in Paint. Linseed oil dries more rapidly and with a harder film than other types of oil, and is therefore preferred for general work. Raw oil is used in most prepared paints; boiled oil is used for special types of paint where a glossy surface is required. The normal price of linseed oil is 60 cents per gal, altho the price often goes as high as $1. Soy bean oil, which may be pressed from the soy bean, grown extensively in China and in the southern part of this country, has been proposed as a substitute for linseed oil. It is rather slow in its drying properties and requires admixture with linseed oil or a large amount of drier. Refined menhaden oil has come into some use for paints which are subjected to exposure along the coast or for special technical purposes. Corn oil and cottonseed oil dry very slowly and paints in which they are used become darkened by adherence of dust particles. Chinese wood oil, which is expressed from the nut of the Chinese tung tree, when heat-treated with the proper driers, is very valuable for certain types of waterproofing paints. Petroleum oil dries slowly and is injurious to most paints. Rosin oil disintegrates very rapidly and should not be used in paints for wooden surfaces.

Thinning Liquids. Turpentine is used as a thinner for linseed oil paste paints. It aids in the penetration and drying of the paint. High boiling point petroleum spirits, which are often referred to as mineral spirits and

Am. Soc. Test. Mat. Specifications for Oils Used in Paint

RAW LINSEED OIL

which have the same boiling point and gravity as turpentine, are being widely used in place of turpentine and with exceedingly good results. Water white coal tar benzol is used in special paints and as a base for paint removers.

Specifications for Turpentine:

1. These specifications apply both to the turpentine that is distilled from pine oleoresins, and commonly known as gum turpentine or spirits turpentine, and to the turpentine commonly known as wood turpentine that is obtained from resinous wood, whether by extraction with volatile solvents, or by steam, or by destructive distillation.

2. The purchaser, when ordering under these specifications, may specify whether gum spirits or wood turpentine is desired. The turpentine shall be clear and free from suspended matter and water.

3. The color shall be STANDARD or better. The term STANDARD refers to the color recognized as standard by the "Naval Stores Trade." Turpentine is of standard color when a depth of 50 mm in a perfectly flat polished bottom tube approximately matches a No. 1 yellow Lovibond glass.

4. The specific gravity shall be not less than 0.862 nor more than 0.872 at 15.5° C (60° F).

5. The refractive index at 15.5° C (60° F) shall be not less than 1.468 nor more than 1.478.

6. The initial boiling point shall be not less than 150° C (302° F), nor more than 160° C (320° F).

7. Ninety percent of the turpentine shall distill below 170° C (338° F).

8. The polymerization residue shall not exceed 2% and its refractive index at 15.5° C (60° F) shall not be less than 1.500.

Driers for Paints. Lead and manganese in the form of oxides are boiled with oil in order to form salts or oil-soluble soaps. They act as catalytic agents in carrying oxygen from the air to the oil, thus causing rapid drying. The lead should be in greater percentage than the manganese when used together. Zinc sulphate, zinc resinate and lead acetate are other forms of driers which are used for special paints.

Paints in Paste Form. White lead contains approximately 9 lb of oil to 100 lb of paste. When used in a paint, there should be added from 4 to 5 gal of oil for reduction. Zinc paste contains approximately 16 lb of oil to 100 lb of pigment. When used, there should be added approximately 6 gal of oil or liquids.

Application of Paint to Wooden Surfaces. For the application of paint to all types of new wooden surfaces, the wood should first be sandpapered to remove the rough spots. Any knots in the wood will ultimately come thru the paint unless they are first treated by the application of a daub of turpentine or 60° water white coal tar benzol. When the knots have become softened by this application, the paint may be applied to the whole wooden surface. A bond is thus formed between the softened rosin of the knots and the paint. When the paint is in prepared liquid form, from a pint to a quart of turpentine to the gallon of paint should be added for the priming coat. This will cause greater penetration and a hard drying surface. Nail holes, grooves and cracks should then be stopped up with putty and the second and third coats of paint applied. At least 24 hr should be allowed between coats. If a week is allowed, better results will be obtained, as durability depends upon obtaining hard undercoats. When an old surface is to be repainted, any scaled, blistered or alligatored paint should be removed by sandpapering.

Paint Tests. Large wooden test structures erected by the Paint Manufacturers' Association of the United States at Atlantic City, Pittsburgh, Nashville and Washington, and painted with various single pigment paints as well as combination pigment paints, have demonstrated the superiority of the combination pigment paint. The test fence at Arlington, Va., erected by the Am. Soc. Test. Mat. has shown similar results; the report of the inspection committee for 1914 including the following statement: "The panels painted with composite paints containing both lead and zinc pigments show superiority to those painted with single primary pigments."

Comparative Durability of Paints. The addition of color pigments to white paint increases the durability at least 25%. For this reason tinted paints are preferred to white paints wherever durability is the prime requisite.

Spreading Rate and Cost of Paint. Upon new surfaces, prepared paint will usually cover from 300 to 350 ft per gal for the priming coat and from 400 to 700 ft per gal for the second and third coats. This varies with the type and finish of lumber to be painted. The cost of prepared paint averages about $2 per gal. The cost of labor is generally twice the cost of the paint.

7. Decay and Preservation of Stone and Masonry

Causes of Decay. The decay of stone is due to constant exposure to the elements, cracking caused by freezing of fissure-entrained water, seepage of water-soluble constituents, etc. Porous stones, such as sandstone, are less affected by freezing than those having capillary pores, but are not as durable as the highly non-porous stones. Granite shows a porosity of about 1%; limestone up to 10%, and sandstone up to 20%.

Preservative Treatment. Stones may be moisture-proofed by brush-coating with a solution made by dissolving 5 lb of paraffin in 100 lb of benzine. Evaporation of the benzine leaves a colorless protective coating of paraffin. Another treatment consists in applying a solution of a metallic salt, such as chloride of zinc, copper, or calcium, or the sulphate of aluminum or chromium, and subsequently applying a coating of ordinary soap which reacts to produce insoluble metallic soaps having high moisture-proofing values. Alkaline solutions of casein are also useful for this purpose. Brush treatment with coal tar, followed by daubing with hot asphalt compositions, is useful for waterproofing.

Concrete may be protected from the effect of alkaline water containing soluble sulphates, which has a marked disintegrating influence, by the application of water-gas tar. Concrete mixed with 10% of ordinary petroleum road oil is also resistant to alkalis. Portland cement-concrete structures of all types, bridges, buildings, walls, etc, may be preserved and highly decorated thru the application of prepared linseed oil paints, such as those outlined under the PROTECTION OF WOODEN SURFACES. If the concrete is damp or freshly laid, there should first be applied a 20% water solution of zinc sulphate which neutralizes any free lime present, thus preventing possible saponification. Two days later the paint may be applied. Prepared paints containing Chinese wood oil are also very useful for this purpose especially if highly glossy surfaces are desired. Waterproofing of underground concrete walls requires the application of special bituminous paints, alternate layers of felt, paper and hot petroleum asphalt, etc.

Cement Drain Tile. Cement drain tile that is to be laid in alkaline soil may be preserved from the disintegrating action of the sodium sulphate by protection with a bituminous coating. Water-gas tar is a very efficient preservative for this purpose. The drain tile may be dipped into the tar, withdrawn and allowed to drain. If desired, color pigments, such as red oxide of iron, may be added to the paint in order to give the tile a more pleasing color. Tile treated in this manner is very moisture-proof and resistant to the action of alkalis.

SECTION 28

FINANCING OF HIGHWAY IMPROVEMENTS

BY

NELSON P. LEWIS

CHIEF ENGINEER, BOARD OF ESTIMATE AND APPORTIONMENT, NEW YORK CITY

VARIETY OF PROBLEMS

METHODS OF FINANCING

EXPENSES TO BE FINANCED

ASSESSMENTS FOR BENEFIT

VARIETY OF PROBLEMS

1. The Rural District

The Highways in Rural Districts have until lately been greatly neglected owing to the facts that they were considered matters of local concern, that the mileage of roads was great in proportion to the number of abutting owners, and that the cost of their improvement was very large in comparison with the value of the property served by them. Even in such districts the conditions varied greatly. Where land was productive and intensively cultivated and where markets or transportation lines to markets were accessible, the cost of road improvement would be more than compensated for by the lessened expense of hauling due to the possibility of greater loads and better speed, but no plan had been worked out to secure such improvements. Where the land was unproductive, population sparse, and traffic light, the expense of better roads was beyond the means of the district. In either case the traffic was almost entirely local and the township, county or state did not feel called upon to bear the cost of better-

ments which did not promise to be of advantage to the entire political unit. The advent of the motor vehicle has changed these conditions. The urban population is spreading out into the rural districts, frequently to establish homes and more frequently for their pleasure riding. Improved methods of agriculture with better returns both in quantity and in prices have placed the motor car within the reach of the rural population and the demands for general highway improvement have become insistent and irresistible.

State Aid. The first response to this demand was thru state aid, the cost of road improvement being divided between the state, the county, the township, and in some cases the abutting land owners. The tendency has been to consider such improvements more and more as a general benefit and less and less a local obligation until the state itself has assumed the larger part of the burden. The rural districts, including not only those well adapted to agriculture but those where the land values are negligible and where the principal asset is the scenery, are being covered with a network of improved roads which will result in removing the isolation in which many seemed doomed to dwell and in enabling those living in the cities and towns to know the country as they had not known and appreciated it before. Whether this work should be undertaken and paid for by the state without any contribution from the locality, particularly when the needed funds are borrowed for long terms of years, is at least a debatable question which will be discussed in subsequent articles. While much progress has been made in developing systems of improved highways in the several states, much still remains to be done. In 1911 Baron d'Estournelles de Constant, in speaking of the highway situation in this country, said, "You have no real railways and highways. You think you have but you have not. You have only fragments. You have not the immense network of roads necessary for the activity and productivity of your country. Get to work; for this immense task you will never have too much money, too many men, too much time." In discussing the relative demands for new highways for purposes of business and pleasure, Clifford Richardson, in a paper presented to the Third International Road Congress held in London in 1913, distinguishes between what he calls utilities and satisfactions. In the former class he places roads which are improved in order to cheapen transportation and to bring the producer nearer to the market. In the latter he includes improvements which are prompted by the demands of automobile users and others who wish to secure good roads for pleasure traffic. He points out that motor vehicles are the principal cause of the rapid deterioration of road surfaces and that such improvements should be largely paid for by those using motor cars. If this be true, the policy prevailing in Great Britain of placing a heavy tax on gasoline or petrol apppears effectively to reach those who are responsible for the wear and tear on highways. From this source the British Government in 1913 raised more than $6 000 000, which sum was turned over to the British Road Board for use in general highway improvement.

2. The Town

In Small Centers of Population where there is a certain amount of business drawn from the surrounding country and a considerable community of interest, the situation is different. The main street or streets of the town are frequented by nearly all of the inhabitants and all have an interest in making their roadways passable and the roadsides as attractive as

possible. The improvement of the roads is therefore a matter of general public concern. Many of these towns have grown up about a village green or a public square around which, or sometimes in which, the town hall and the churches have been grouped. All of the public activities, including, perhaps, recreation and amusement, center here, and it will be conceded that the condition in which the open space, the roadways and sidewalks are kept is a matter of public concern, and it is argued that the cost of their improvement, maintenance and repair should be borne by the town. The most valuable property will be that fronting upon this square, so that if its improvement and upkeep result in special benefit to the surrounding property that property will bear a correspondingly large part of the burden. If the main street of the town needs widening, straightening, extending or a surface improvement, the benefit will again apply to the entire community. It is customary in such localities to improve one street at a time, beginning with those of greatest importance, a special tax being levied for each improvement, and in the course of time nearly all of the streets will have been improved in turn, each property owner having contributed in proportion to the value of his holdings to the improvement not only of his own but of his fellow townsmen's streets, and everybody is as well satisfied as possible where the payment of taxes is involved.

Development of a Street System. But as the town grows the number of what are called main streets increases; other centers of activity or recreation are needed. The new projects will still result in some general benefit but in a large measure of special benefit. The effect upon the property in their neighborhood will be proportionately greater and more exclusive than in the case of the first village green or town square. The entire community will doubtless feel the benefit of the new improvements but in less degree, as they tend to create new centers and diffuse rather than concentrate business and other activities. The town can still afford to contribute toward the expense, but the fair portion to be assumed by it will be less in proportion to the amount of special benefit resulting to the particular locality.

Improvement of Pavements. With this growth there is a demand for a more substantial character of pavement on the principal streets. The broken stone or gravel which formerly answered every purpose must be replaced by a smooth surface, such as bituminous or brick, and while the interest of the entire town in such an improvement is still keen, the benefit is somewhat more localized and the owners of property on streets some blocks away who use the original main street less frequently are more reluctant to contribute towards the cost of the new pavement. To avoid the burden of a special tax, resort is likely to be had to a loan which seemed such an easy way to raise money to pay for the water supply or sewers which may have already been installed, and the policy of borrowing instead of paying cash for street improvement is inaugurated.

3. The Small City

The Small City, as the term is here used, is one of less than 100 000 population. The transition from the town to the small city is gradual and the line of demarcation between the two is indefinite. There are instances of towns of 15 000 or 20 000 inhabitants which are called villages and are governed by the administrative machinery common to villages, while many so-called cities are far less populous. In many of these centers of

population, whether they are called villages or cities, the community of interest, characteristic of earlier days, still persists. It is when this common interest is chiefly concerned with the larger activities and enterprises, such as water supply, police and fire protection, the disposal of wastes, and the care of dependents, incompetents and criminals, while those whose benefits can be localized attract increasingly less general attention, that the town is classified as a city. There will be a limited number of streets in which most of the business will be carried on and the condition of them will continue to be a matter of general concern. The people will have become accustomed to increasing annual tax budgets and will not scrutinize them as closely as they did in the village days; they will probably have resorted to the use of the city's credit in order to raise funds for various purposes and the annual burden of providing interest and sinking funds for their obligations or for retiring such serial bonds as may have become due will not have become so serious as to deter them from further use of the city's credit in order to provide new pavements.

Special Assessments or Loans. Those who have seen other streets improved one after another from the general town funds and have contributed their share toward the expense will resent being called upon to pay for their own pavements. It will not be until the demands upon the city's revenues for other general purposes have increased to such a degree that they see the annual tax budget growing at a rate considerably greater than the population that the necessity of levying special assessments for every improvement which results in distinctly local benefit will be realized. The small city may, after much discussion, have resolved to undertake the construction of some important boulevard or parkway in connection with the development of a park system, or it may have decided that it, like some of the larger cities, should create a civic center, and the interest in either or both of these projects will be so general that, while the idea may be encouraged by those whose property will be required for the purpose or who may own property which will be substantially increased in value, the reasonableness of imposing a special share of the burden upon property so affected is seldom suggested and the only method of financing seriously considered will be by another loan for which the credit of the city will be pledged.

4. The Large City

Development of Large Cities. The large city is frequently created by the consolidation of a number of towns and villages and in it all of the conditions described in the two preceding Articles will be found. The present City of New York, when established, included what were previously three cities and a score or more of towns and villages. To administer the affairs of these different communities under uniform laws which had been evolved to fit conditions existing in the largest city of the United States was one of the most difficult problems in city government that had ever been presented. There have been certain instances of municipal coöperation, as in Boston, where a number of cities and towns have been brought together within a metropolitan district for the exercise of such functions as the development of park, water supply, and sewerage systems, but where they retain their autonomy in the administration of their local affairs, among which is included the construction, maintenance and repair of their highways. Even in London there are 29 city or borough governments within the administrative county, each one of which determines

what sums it shall spend in the care of its streets, altho the London County Council exercises jurisdiction over certain arterial highways and contributes to the expense of their improvement.

Local and General Assessments. Where highway administration is centralized and conducted under laws which apply to the entire city, parts of which are intensively developed, others suburban and still others rural, some very difficult problems will arise. Streets in the older parts of the city may have been paved and repaved with substantial pavement at the expense of the abutting owners until it is believed inequitable to ask them to pay for any more surface improvements, and laws may have been passed forbidding further paving assessments where a modern pavement has once been laid and paid for by local assessment. The taxpayers in a suburban district, where the streets may have been improved in the manner described in Art. 2, are likely to insist that they, too, have paid for road surfaces which were adapted to their needs and, inasmuch as they are called upon to contribute to the cost of pavement renewals in the older parts of the city, they are entitled to the same consideration. In the undeveloped sections where no pavements have yet been laid, efforts will be made to secure for the first pavement the cheapest type which can be constructed and which will still exempt them from further assessment.

Classification of Pavements. In New York, where there is a prohibition against assessments for repaving, an attempt has been made by statute to meet such cases by classifying pavements into those which are permanent and those which are preliminary, the term permanent not being used in a literal sense but as indicating the character of pavement which will exempt the abutting owners from further assessment.

New York Charter Provision. "Pavements which were laid or authorized between January 1, 1898, and June 20, 1910, the cost of which was assessed upon the property deemed to be benefited, and pavements, the cost of which was paid for by assessment, or by the owners of adjoining property, or by local taxation, or by bond issues paid by the locality prior to January 1, 1898, shall be deemed to be permanent pavements. No street or portion thereof, that shall have been paved with a pavement deemed a permanent pavement or that hereafter may be paved with a permanent pavement paid for wholly by assessment shall be repaved at the expense of the adjoining property owners, unless a majority of the owners of the property on the line of the proposed improvement shall petition for such repaving at their expense by assessment. Whenever a street paved with a preliminary pavement shall be repaved, the repaving shall be done with a permanent pavement, unless the owners of property on the line of the proposed improvement petition the Local Board having jurisdiction for a second preliminary pavement, to be laid at the expense, by assessment, of the adjoining property owners, and in such event a second preliminary pavement shall be laid if said Local Board so orders, and the Board of Estimate and Apportionment consents. Whenever a permanent pavement shall be laid to replace a preliminary pavement laid, in whole or in part, at the expense of the property owners by assessment or to replace a permanent pavement laid at the expense, in part only, of the property owners by assessment and the cost of the replacing pavement shall exceed the amount assessed upon the property deemed to have been benefited for the pavement replaced, the excess of such cost shall be assessed upon the property deemed to be benefited, and the balance of the cost of the replacing pavement shall be borne and paid by the city; but in no case shall

the cost of a second or subsequent preliminary pavement be so deducted from the amount to be assessed for the laying of a permanent pavement. The class of a pavement shall not be changed after the same is laid."

Classification adopted by the Board of Estimate and Apportionment acting under authority given by the act.

Permanent pavements. The following pavements laid on a Portland cement-concrete foundation 6 in or more in thickness: Stone block, wood block, asphalt block not less than 3 in in thickness; sheet-asphalt with wearing surface not less than 2 in in thickness and binder not less than 1 in thick, vitrified brick and iron slag.

Preliminary pavements. Stone block on sand foundation, asphalt block not less than 2 in in thickness laid on a cement-concrete foundation not less than 4 in thick, sheet-asphalt laid on a cement-concrete foundation not less than 4 in thick, bituminous concrete and bituminous macadam; also cement-concrete and water-bound broken stone, not less than 6 in thick. under conditions to be prescribed by the Board. It will be seen that the statute arbitrarily classifies as permanent all pavements which were laid before a certain date and paid for in a certain manner with no regard whatever for the foundation, the materials used or the character of the work.

Boulevards and Parkways. Every large city has certain wide streets which are described as boulevards or parkways, the improvement of which is usually carried out at the expense of the city at large under the theory that they are of general benefit. Such streets and even others which, by reason of their widths and positions, are by no means exceptional are sometimes placed under the jurisdiction and control of the park authorities for the sole reason that they may, as a result of such control, be improved at general expense and the abutting owners may escape the burden of assessment which, under other circumstances, would be placed upon them.

Streets in the Office Building, Shopping and Hotel Districts are so generally used that it is commonly conceded that their repaving is a proper charge against the city as a whole. It is true that the most expensive property in the city and the greatest producers of revenue from taxation are found in those districts and their contribution to the general city budget is so large that it is reasonably argued that they are entitled to exemption from local assessment for the replacement of pavements. But the demands upon the city's resources are so great that repaving cannot always be done as promptly as it is actually needed. The value to such property of thoroly good, smooth and quiet pavements is so great that the cost of such frequent renewals as would always keep them in the best of condition would, if imposed entirely upon the owners, be trifling in comparison with the added attractiveness to tenants, shoppers and guests and the increased rentals which the property would command.

5. Responsibilities of the Highway Engineer

Province of the Highway Engineer. The preceding outline of the general problems of financing highway improvements and the more specific discussions in the following Articles may be thought to be outside the province of the highway engineer. There is a notion quite generally prevalent, even among engineers themselves, that their proper function is to plan and execute the work, but that the duty of determining general policies,

more particularly those relating to financial considerations, belongs to the administrative heads of the highway department whether of a state, county, township or city. Such officials are commonly appointed for brief terms of office or, when the term is nominally longer, some excuse is quite frequently found for terminating it after a change in administration. Each new commissioner or superintendent, or whatever he may be called, will have some ideas of his own even tho, as is too frequently the case, he may be entirely inexperienced in this kind of work. His ambition is to impress these ideas upon the organization of which he is the head for the time being and he may think it especially desirable to discredit the acts and policies of his immediate predecessor.

The Highway Engineer as a Subordinate. The engineer, who, tho likely to be continued in office, is merely a part of the permanent organization, is quite likely to accept the new ideas as to organization or methods of financing as an incident to a change of administration, even tho he knows them to be essentially unsound. Should he allow what he knows to be unsound financial methods to be adopted without entering a vigorous protest? If contracts and specifications were prepared that would be obviously wasteful or needlessly expensive or would probably result in damage claims or litigation which would increase the cost of the work, he would doubtless feel it his duty to point out their defects. There is no reason why he should not similarly protest against unsound and reckless plans for the financing of highway improvements. His advice may not be taken the first time such objections are made, but they should be placed on record and when their soundness shall have been demonstrated his next protests are likely to receive more consideration. Engineers appear altogether too timid about discussing such features of their work in their periodical reports. They are usually ready enough to discuss what are commonly admitted to be the strictly engineering features of their work and are beginning to include such subjects as the organization of the engineering staff and cost data, but the questions of how the state or the city or the individual property owner who is benefited is to pay for the work, the relation of the life of the road or pavement to the period during which it is to be paid for, and just what this means to the state, the city or the individual, are subjects which he discreetly avoids. His experience should, however, render him peculiarly well qualified to discuss and advise upon these subjects. There have been frequent instances of the greatest recklessness in financing highway improvements, and in many cases these questions have been determined by legislative enactments before the engineer has had any connection with the work. Such improvements are now being carried out on a much larger scale than they formerly were and by organizations which are in existence and well developed and which have ample opportunity to impress their ideas upon the entire project in its financial as well as its engineering features.

Responsibility of Highway Engineers. The engineer has a distinct responsibility for every phase of the work and he should not shirk it. If the road-improvement or street-paving policy is discredited thru bad financing or an unjust distribution of the burden of expense, if the funds are used to create an extensive system of highways and nothing is left to care for them after they are built, if the people who are now insistent upon highway improvement find that the roads and streets are worn out years before they have finished paying for them, the public may conclude that the benefits they expected are not worth the price they have to pay and

will refuse to go further. The engineers as well as the administrative officers will suffer from such an unfortunate situation, so that self-interest as well as professional pride should prompt them to assume a stronger position than they have heretofore taken with respect to this phase of the highway problem.

METHODS OF FINANCING

6. Long-Term Bonds

Present and Future Benefit. The argument most frequently advanced against the assessment directly upon the abutting property of the cost of highway improvements is not only that all street improvements are of general benefit but that the benefit will inure to the next generation as well as to the present owners, and that the next generation should therefore share the burden. This argument is made not only with respect to the acquisition of property for new streets and for the widening and straightening of old streets, which are permanent improvements, and for grading, surface drainage, culverts and bridges, which are reasonably permanent, but also for the cost of the pavement itself. The most effective way to accomplish this transfer of the burden or a greater part of it to someone else is to raise the money required for the improvement by the issue of bonds, and the temptation is to make these obligations run for a long term, frequently 50 years.

Increased Cost when Bond Issues are Used. With interest at 4 or 4½%, as has frequently been paid, the total interest payments would be twice or two and one-quarter times the actual cost of the work. The annual amortization charges for 50 years on a 3% basis would be 0.89%, so that for every $1000 of original cost the city or the state would pay $2445 in the case of 4% bonds and $2695 in the case of 4½% bonds. But the roadway surface will have worn out long before the expiration of the 50-year period, yet the public at large will keep on paying. If this apparently easy way of paying for street improvements is once begun it is likely to be continued and to be applied to the payment of the cost of replacing worn-out surfaces. There are many cases where pavements on country roads and city streets will not last more than ten years, and if this policy of financing is continued the public will after 40 years be paying for five different pavements, four of which will have entirely disappeared, and the annual expense during the decade from 40 to 50 years after the original pavement was laid will be 24.45 or 26.95% of its original cost, depending upon whether the bonds carry 4 or 4½% interest. The above estimates relate only to the surface pavement itself and not to the more permanent portions of the work which will have a life much greater than 10 years. In the case of rural highways the results of this policy are equally startling. Road improvements which are now being carried out in many states cost from $12 000 to $20 000 a mile and in some cases even more. With state bonds bearing 4% interest, the total interest and amortization charges for a period of 50 years will amount to $29 340 or $48 900 a mile for an initial cost of $12 000 or $20 000. This would amount to from $46 to $76 an acre for all of the land within half a mile on each side of the road. Such roads are commonly 16 ft wide, which is equivalent to 9387 sq yd of surface per mile of road, and the surface of bituminous macadam roads of the type in common use may be assumed to cost an average of 5 cents a sq yd

for maintenance and repair during the first 10 years, and to require complete resurfacing at the expiration of that period. Assuming that such resurfacing costs 60 cents a sq yd, the cost of maintenance for five 10-year periods and of four renewals would amount to \$4.90 a sq yd or \$45 996.30 a mile. If this be added to the total interest and amortization charges, the cost of these roads before they are finally paid for would be \$75 336.30 in the case of a road which originally cost \$12 000 a mile, or \$94 896.30 if the initial cost were \$20 000 a mile, these totals amounting to \$118 or \$148 an acre for the area extending ½ mile on each side.

Bond Issues for Surface Renewals. If the state were to raise the funds for the decennial renewals by 50-year bonds instead of providing it in the annual budget, it would at the end of 50 years have saved \$22 528.80 a mile in direct appropriation for four surface renewals but it would have paid \$27 541.46 in interest and amortization charges, making the total cost of the road \$80 348.96 or \$99 908.96 a mile, which is equal to \$126 or \$159 an acre for the area already described, while there will still be the sum of \$27 541.46 a mile in interest and amortization charges on the funds borrowed for periodical renewals which will not be entirely paid off for another 40 years.

Relation of Total Cost to Land Values. The acreage value of the land along such roads will be far less than the sums above named, while the system of financing road improvements in this manner is so monstrously absurd that it is surprising that it should even have been considered. Yet great cities and states have started comprehensive schemes of street and road improvement on this very basis. The folly of such a policy will undoubtedly be apparent before they have gone much further.

7. Short-Term Bonds

Advantages of Short-Term Bonds when issued for highway improvement may be generally considered as those whose term will approximately correspond with the life of the improvement for which the funds are to pay, so that the road will not be worn out before it is completely paid for. Some portions of the work will last longer than others, and bonds which will correspond in their term with the average life of the improvement may properly be considered short-term bonds. In the case of a road improvement which is to be entirely paid for by bond issues, if 20% of the cost is represented by such expenses as widening, grading and substantial culverts, that portion may be considered as virtually permanent, and 50 years would not be an unreasonable time in which to pay for it; if 20% were for curbing and for gutter paving which might be expected to last for 20 years, bonds issued for a corresponding term for this part of the work would be fair and reasonable; if the road surface represented the remaining 60% of the cost and the surface would require replacing in ten years, it would be unwise to borrow the money to pay for that part of the work for a longer period. The average life of the entire improvement might in such a case be considered 20 years and it might therefore be considered fair to issue 20-year bonds to pay for it. There is a fallacy, however, in this argument as the interest and amortization charges will be constant for the entire 20-year period, notwithstanding the fact that a part of the work, representing 60% of the total cost, will have been worn out in half that time, altho there will still remain a portion representing 20% of the

total cost which will last for 30 years after it is entirely paid for. A more conservative plan would therefore be to limit the bonds to 15 years for improvement of the kind described.

Annual Payments for Interest and Sinking Fund. In cities, the cost of the first pavement is commonly assessed upon the abutting property and the city at large pays for replacements, and the funds for the purpose are almost always raised by bond issues. While the life of such pavements varies greatly, depending upon their character, the kind of foundation used, and the intensity of the traffic to which they are subjected, it is probable that their average life will not exceed 15 years, and this period seems a logical one for the term of the obligations which may be issued to provide funds for their construction. Amortization charges for this period on a 3% basis amount to 5.38%, while bonds for so short a term will probably carry 4½% interest at the present time, making the total annual contribution to care for them at maturity 9.88%. If the bonds are for but 10 years and carry 4½% interest, the annual payments for interest and sinking fund would be 13.22%. As the terms of the bonds are shortened, the total annual expense grows impressively larger but it must be remembered that there is less overlapping of the different issues and, after this policy of paying for highway improvements by bond issues has been followed for a period corresponding with the term of the bonds, the total amount to be provided to care for the outstanding debt will be considerably less in the case of the short-term bonds. For instance, if a constant sum of $200 000 a year were borrowed for highway improvements and if 50-year bonds were issued for the purpose, at the end of 50 years there would be $10 000 000 of these bonds outstanding, and during this time the annual interest and amortization charges would gradually increase until it reached $489 000, when it would remain constant. If, however, the funds were raised by the issue of 10-year bonds, there would be $2 000 000 outstanding at the end of 10 years, during which time the annual interest and sinking-fund charges would increase until at the tenth year they reached $264 400, when they too would remain constant. Under the latter policy there would at the end of 50 years be an annual saving to the taxpayers of $224 600 a year. It may be said that these periods are so long that such a discussion is academic, but street and road improvements are going to continue for an indefinite time, our cities and states hope to remain solvent and must meet their financial obligations, and debts of this kind must be paid in full, so that the actual facts should be squarely faced.

Need of Control over Methods of Financing. In the United States there is no limitation placed upon the terms for which our cities and states can borrow money other than the willingness of the investing public to take their obligations. The need of some controlling authority is becoming obvious. This frequently exists in other countries. In Great Britain it is vested in the Local Government Board, which is a Cabinet department and the consent of which is required before any city, town or county can issue its debentures. All of the facts must be submitted to this Board, including a statement of the purpose of the loan, a description of the improvements to be undertaken, an estimate of the cost, and the probable life of each particular part of the work, and the Board in giving its consent specifies the term for which the funds may be borrowed, such term corresponding as nearly as possible with the reasonably estimated life of the structure or work.

8. Serial Bonds

Advantages and Disadvantages. To distribute the cost of street or road improvements over a term of years and at the same time to avoid the necessity of accumulating large sinking funds which return small rates of interest, resort is frequently had to serial bonds. In this case provision must be made for retiring a certain part of the issue each year and for interest on the bonds which remain outstanding. If $100 000 of 4% bonds are issued in serial form, $4000 falling due each year, the provision which must be made to care for bonds to be retired and interest on those outstanding will be as follows: first year, $8000; eleventh year, $6400; twenty-first year, $4800; twenty-fifth year, $4160. One advantage of this plan is that as part of the work is worn out and the value of the improvement becomes less there is a corresponding reduction in the annual burden. It is important, however, that the series shall be so arranged that the amount outstanding at any time shall not exceed the actual value of the original improvement at that time. When serial bonds are issued in such a manner that the last bonds will not be retired for a long term of years, or a term far in excess of the probable life of a large portion of the work, the plan is uneconomic and pernicious.

Maine Plan. A novel scheme for financing road improvements is that adopted by the State of Maine. Under a law enacted in 1913, serial bonds, the last of any series being payable within 41 years, were authorized to be issued in amounts not exceeding $500 000 in any one year, with the provision that not more than $2 000 000 of these bonds should be outstanding at any one time, the bonds bearing interest not exceeding 4%. The extraordinary provision of this law is that these bonds are to be cared for from the receipts for automobile licenses. With $2 000 000 of bonds outstanding and one-fortieth of this sum to be retired in any one year, $130 000 would have to be provided annually for interest on the outstanding bonds and for the retirement of those falling due. In 1912 the receipts from automobile license fees was about $100 000. This sum was increased the following year to $140 000 and in 1914 to about $180 000. If these increases continue there would appear to be some margin which could be devoted to the annual expenses of the repair and maintenance of these roads, but the capitalization of estimated receipts from this source, which prudence would dictate should be devoted to upkeep, appears to be a dangerous method of financing road improvements, especially in view of the fact that it is highly probable that, before the last of any series will be retired, it will become necessary to replace the road surface several times, and to meet this expense the entire receipts from automobile licenses over and above the amount required to care for the bonds would doubtless be required, and even this would probably be found inadequate.

Maryland Plan. In marked contrast with this is the policy of the State of Maryland, which is paying for its highway improvements by 15-year bonds, so that when the road surfaces are worn out there will be little, if any, outstanding debt incurred on their account, provided that such renewals of the surface as may be required before that time are paid for from general appropriations.

Application to County-Road System in Illinois. An excellent illustration of the use of the serial-bond plan to finance a system of highways is that adopted by one of the counties in Illinois, where 4% bonds to the amount of $1 500 000 have been authorized for a system of county roads; $75 000

worth of these bonds is to be retired each year so that at the end of 20 years the roads will have been paid for. It has been estimated that the annual cost of providing this road system per acre of farm land, which has an assessed value of a little over $30 an acre, will be a maximum of 10⅛ cents in the third year, when the entire improvement will have been completed and the interest charges reach a maximum, and that this will gradually decrease until in the twentieth and final year the cost for each acre of farm land will be but 6⅝ cents.

9. Annual Appropriations

Changing from Credit to Cash System. When highway improvements are not paid for with borrowed money, that is, when they are paid for in cash, resort must be had to taxation, the amount to be expended each year being included in the annual budget. It is apparently so much easier to pay with borrowed money with the idea that the next generation should share the expense, and those responsible for budget making are so sensitive to the criticism that invariably follows an increase in the tax rate, that it is difficult to secure adequate budgetary appropriations for highway improvements. After a long period of borrowing and when provisions for interest and sinking-fund charges represent a large part of the annual tax budget, the need of a change of policy becomes obvious, but with a long period of payments on outstanding obligations to look forward to it is difficult to change to such a basis.

New York's "Pay-As-You-Go" Plan. The City of New York has issued its bonds to such an extent that the debt service, or the annual interest and amortization charges, amounted to 37% of the total sum raised by taxation in 1914. A change in policy was then determined upon to be brought about in 4 years in the following manner: For all revenue-producing enterprises, such as water supply, transit lines and improvements of the water front, 50-year bonds are to be issued as heretofore; for all non-productive improvements, such as repavements, bridges and public buildings, three-fourths of the funds required during 1915 are to be raised by the issue of 15-year bonds and one-fourth by short-term loans provided for in the tax budget for the following year. During the year 1916 one-half of the funds needed for these purposes are to be raised by the issue of 15-year bonds and one-half by short-term notes provided for in the budget for the following year. In 1917 one-fourth of the requirements will be met by the sale of 15-year bonds and three-fourths will be paid for as above described, which is equivalent to cash; while in 1918 and thereafter the entire expenditures for non-revenue-producing improvements will be paid for without incurring any bonded debt. Inasmuch as a very large proportion of the outstanding debt of New York City will run for from 30 to 50 years, the debt service budget will decrease very slowly and the change to a cash basis will necessarily involve a substantial increase in the tax rate. This is a fair illustration of the difficulty of changing from a credit to a cash basis in financing improvements which do not produce any direct revenue.

Prompt Completion of Highway System. In small cities, where the mileage of pavements is small and a considerable annual expenditure for replacements is not needed, the advantages of budgetary appropriations are not so obvious, but in a large city or a state, where the annual expenditures are likely to run into the millions, they are quite apparent. It was shown

in Art. 7 that in 10 years after the commencement of yearly issues of 10-year bonds the annual debt charges would exceed budgetary appropriations to the same amount by 32.2%, while in the case of 50-year bonds it will be found that 20 years after beginning to raise funds in this way the interest and sinking-fund charges will almost exactly equal the annual cash expenditure and from then on it will exceed it by an increasing percentage every year for another 30 years. Ten or even 20 years are very short periods in the life of a city. The creation of a state system of highways is somewhat different. There are insistent demands that such a system be developed within a very few years. Annual appropriations to the amount required to provide such a system in, say, 5 years would be out of the question. The people of the State of New York, for instance, voted $50 000 000 of bonds for highway improvements in 1905 and another $50 000 000 in 1912, all of these bonds running for 50 years. If they pay 4%, this will mean an annual tax of $4 890 000 for interest and sinking-fund charges for two generations, to say nothing of the huge budget required for maintenance and periodic renewal of the road surfaces. Yet annual appropriations of this sum would have provided the same system of improved roads in 20 years and there would have been no debt saddled upon the next generation. The immense sum authorized to be raised by bonds could not be effectively expended in less than 10 years, or half the time within which the entire improvement could have been carried out at no greater annual burden and without a dollar of debt.

10. Local Assessments

Roads. In view of the enormous demands upon the resources of cities and states for purposes which are of general benefit, it is necessary either to find new sources of revenue by means of special taxes or to raise at least a part of the cost of improvements which are of local benefit by direct assessment upon the property so benefited. Few, if any, improvements involve so large a proportion of direct benefit as those relating to highways. In the rural districts the property fronting upon the roads is of such relatively low value that assessments for any considerable portion of the cost of their improvement cannot be imposed upon it, but the county and township could properly be required to share the burden with the state and a small assessment could with equal propriety be placed upon the land fronting upon the road. This was the theory of the first state aid laws and it was so sound and just that it seems unwise to have abandoned it. Improvements under this law, however, were initiated upon petition and the improved sections of road were not contiguous, while the demands were insistent for a complete system of good roads traversing the state in all directions, and to meet these demands the state itself was obliged to undertake the task of providing a comprehensive system of good highways without depending upon the local authorities.

Streets. In cities the conditions are different. The abutting property is so valuable that the cost of good pavements is but a small proportion of the land values, while that value is at once further increased as a result of the improvement. In most large cities the entire cost of the first pavement is assessed directly upon the property, and in some cases the cost of repaving is similarly assessed. In Rochester, N. Y., the entire cost of all pavements, both original and repaving, is assessed upon the abutting property. In Utica, in the same state, one-third of the cost

of the original pavement and the subsequent renewals is borne by the city and the remainder is assessed according to benefit. In the American City, November, 1914, there is a compilation of the method of assessing the cost of acquiring new streets, of widening existing streets, and of surface improvements. While in the smaller cities the cost of the first paving is often paid by the city at large, Washington, D. C., is the only city of considerable size that follows this practice, and conditions in this city are so exceptional, owing to its very wide streets, that it cannot be taken as typical. The benefit of good pavements to the abutting property is so great that the cost of substituting a new surface for one which is worn out could often be assessed upon the abutting property without great hardship. Where such property has a very high value the expense of periodic repaving of the streets upon which it fronts would actually be much less than its share of the general expense if paid by the city at large, whether by budgetary appropriations, short-term bonds, or long-term bonds. New York City, with its enormous expenditures for pavement replacements and its very high real-estate values, may be exceptional, but an analysis of the cost to individual property under several methods of financing repaving will show startling results. It is assumed that the first pavement laid will have been provided with a substantial foundation which will serve for several subsequent surfaces. The prevailing prices for pavements of different kinds are used and the life of the surface is estimated to be from 10 to 18 years, according to traffic conditions, and the cost of each new pavement is divided by the years of its estimated life, each parcel being charged with the paving of one-half the roadway of the bounding streets, except the space between surface railway tracks and 2 ft outside of the rails, which is cared for by the traction companies. It is also estimated that the city will expend $5 000 000 annually for repaving, and the share of the particular property of the interest and sinking-fund charges is that which would be called for at the expiration of a term of years equal to the terms of the bonds.

An Office Building occupying an entire block bounded by four streets, is assessed for taxation at $12 425 000. The cost of renewing the pavements on each of these four streets at the expiration of their reasonable life if made in equal annual payments would be $354 a year, while the share of this property of a $5 000 000 annual appropriation would be $7970.64, and its annual contribution on a 10-year bond and 50-year bond basis respectively would be $10 536 40 and $19 482.40.

A Club House occupying a corner fronting on two streets paved with asphalt has an assessed value of $115 000. The annual expense to it of replacing pavements at the end of their reasonable life would be $30.56, while its contribution to a $5 000 000 annual appropriation would be $73.77, and its share of the same provision for repaving on the basis of 10-year or 50-year bonds would be $97.52 or $180.32.

A Private Residence with a Frontage of 100 Ft but not a corner, and extending thru the block, and thus fronting upon two streets, is assessed at $115 000, and the cost to it of pavement restoration by direct assessment would be $36.12 annually, while its contribution toward the other methods of financing repaving would be precisely the same as that of the club referred to above, its assessed value being identical.

A Block of Eleven Attached Houses located on a corner is assessed at $260 000 and its share of repaving by direct assessment would be $94.40 annually, while its contribution to annual appropriations, 10-year bonds, and 50-year bonds would be respectively $166.79, $220.48, and $407.68.

A House Occupying a Lot 20 Ft Wide in a street accommodating a double-track surface railroad has an assessed value of $10 000. The cost to it of repaving the space not cared for by the railroad company would be $2.40 annually, while its share of annual appropriations, 10-year bonds, and 50-year bonds would be respectively $6.41, $8.48, and $15.30.

A Small Detached House on a 40-Ft Plot fronting on a street 60 ft wide has an assessed value of $4200. In this case its share of renewal of an asphalt pavement by direct assessment would be $5.55 a year, while its contribution toward annual appropriations, 10-year bonds, or 50-year bonds would be respectively $2.69, $3.56, or $6.59.

Financial Advantages of Direct Assessments. In all of the instances above cited, except the last, it will be cheaper for the property to pay a direct assessment for renewing the pavement on the abutting street than to pay its share according to its taxable value of annual appropriations, 10-year bonds, or 50-year bonds. With respect to the modest detached house on a 40-ft plot, it is not improbable that by the time the first pavement is worn out and it is necessary to replace it, the assessed value of this property will have increased to such a point that even in this case its share of the burden of restoring pavements with borrowed money will be less than if it were assessed directly for the expense of replacement.

11. Reckless Financing

Methods of Reckless Financing. References have been made in the preceding Articles to methods of financing highway improvements which without exaggeration may be called reckless. To borrow money to construct roadway surfaces which will wear out long before they are paid for, to apply the same methods of financing to the portions of a road or street improvement which are permanent or which will last for a long period of years, and as to those portions which will be short-lived, to spend large sums for construction without proper provision for maintenance, to save on foundations and drainage when they are necessary to insure a reasonable life for the roadway surface, to use or to capitalize receipts which should be devoted to maintenance and divert the funds to new construction without provision for upkeep, to embark upon any extensive scheme of highway improvement before the ultimate cost has been carefully estimated and a definite plan has been worked out, not only for progressive construction but also for maintenance, all or any of these show lack of good business sense and, judged by these standards, many, if not most, of the extensive highway improvements which have been undertaken are characterized by a certain degree of recklessness.

General and Isolated Improvements. The value of a system of improved roads depends upon its completeness and the continuity of the various routes and in no small degree upon the promptness with which the entire system can be created. The more complete the system and the better the articulation the greater the general benefit, and hence the justification for a resort to general taxation whether by annual cash appropriation or by borrowing for a reasonable term of years. Where isolated pieces of road are improved and the direct connections between them are not provided the benefit cannot be general and resort to general taxation or loans cannot be justified. There have been numerous instances of recklessness in financing highway improvements which by comparison make any of the methods heretofore described appear extremely conservative. Several examples will be cited.

A Flagrant Case of Term Bonds Unloaded upon a City. In 1865, the Legislature of the State of New York authorized three of the towns of Westchester County to raise by loan the sums of $3500, $6500, and $2500 respectively, which sums were to be appropriated to "making, grading, extending and regulating" a certain highway beginning at the Harlem

River and passing thru the three towns named. The act provided that each town should issue bonds for the amount required to meet the cost of that part of the improvement within its limits and that these bonds "shall bear an interest of 7% per annum payable annually, and they shall be so drawn as to become due in sums not exceeding $1000 in any one year." This means of securing the improvement of what was then a main highway appeared reasonable enough and it seemed probable that whatever debt might be incurred would soon be liquidated. In 1868, however, the law was amended by substituting for the sums named for each town the words "such sums as may be necessary." The town which was first authorized to spend $6500 actually expended, or at least raised by issuing its bonds, the sum of $112 500, some of these bonds being in denominations of $1000 but the greater portion of $500 each. There were altogether 178 different bonds, the last one of which will become due in the year 1980. The town which was originally authorized to issue $3500 in bonds actually issued its bonds to the amount of $278 000, all of these having apparently been in $1000 denominations, as the last one will fall due in the year 2147. The two towns above referred to have since become a part of the City of New York and that city has been obliged to assume all of the obligations of the towns, so that in New York's tax budget there appears each year provision for paying off one of the bonds of each of these towns, together with interest at 7% on those which remain outstanding; that is, while the first act provided that two towns, now part of the City of New York, should incur a debt aggregating $10 000 which was to be entirely paid off in not more than 13 years, an actual debt of $390 500 was incurred and saddled upon the City of New York in such a fashion that it could not be entirely paid for 278 years after the first bonds were issued.

Bonded Debt Incurred Two Days before Annexation to a City. One of the towns of Kings County was to be annexed to the then City of Brooklyn on July 1, 1894. Acting under authority of a special statute, that town issued its bonds to the amount of $500 000, and on June 28th, 3 days before it went out of existence, the town authorities made a large number of contracts for road improvements consisting for the most part of water-bound broken-stone roads. The act provided that the town bonds should be issued as serial bonds in groups of $100 000 each, the first of the bonds falling due not less than 10 nor more than 11 years from the date of issue and being retired in 50 successive annual installments. The funds required to meet the interest on the outstanding bonds and the payment of those due was to be provided for in the tax levy of the town every year, there being no assessment upon the abutting property. The town as a separate political unit ceased to exist 3 days after the contracts were made but the city of which it became a part was obliged to assume the obligation, altho it was enabled to provide the needed funds by imposing a special tax annually upon the property within the former town, which became a separate ward of the city. It is safe to say that little, if any, of the roadway surface constructed under this act was in existence when the first bonds of the several groups became due but the debt will not be fully paid until the year 1954.

Other instances of reckless financing might be given, but these two are sufficient to demonstrate the enormous price which will sometimes be imposed upon one or more succeeding generations in order to avoid cash payments for improvements which are obviously of immediate benefit to a particular locality.

EXPENSES TO BE FINANCED

12. Investigations and Surveys

Preliminary Investigations. The physical improvement of roads and streets is not the first work to be undertaken or the first expense to be incurred. When a general scheme of improvement has been decided upon there is usually a feverish desire to begin work on the ground or " to make the dirt fly." The public and the press are insistent that something shall be done that they can see, and they apparently fail to understand that, if the money is to be wisely expended, thoro preliminary studies are necessary. If a state is to devote millions of dollars to general highway improvement, the first thing to be undertaken is a thoro study of the organization best suited to carry out the work; then should come a careful examination of the existing highway system with a view to the selection of the routes which will be of the greatest benefit to the general public. Following this will come investigations and studies to determine where and to what extent modifications of alignment and grade are needed. Before contracts are made there should be a careful investigation of the materials which are available in order to determine whether it will be cheaper in the end to use native materials or to bring others from a distance, even tho the cost of construction be increased. Such expenses as these might properly be considered part of the cost of administration, but, if no separate provision has been made for them, it is far better to draw upon the funds provided for the improvement, whether they be raised by budgetary appropriation or by bond issues or even by assessment for benefit, than to dispense with the preliminary investigations. Without such preliminary work, errors in judgment in the selection of the highways to be improved or in the choice of materials to be used and failure to correct defects in grade and alignment are quite sure to result in an unwise use of some of the funds and in failure to secure the best system of roads which is possible. In the case of a city street system, the preliminary work will be more extensive and will consume far more time and involve much greater expense. The need of topographical surveys, of a careful study of the transportation needs of the future streets, and the main drainage system, of a rational plan not only for the principal and secondary business or traffic streets but also for those which are to be devoted to residential purposes has been emphasized in several of the Articles in Sect. 7. The expense of this work is usually considered as properly chargeable to general administration but in some cities it has been met by the issue of long-term bonds for the reason that it is considered work of a permanent character which will last as long as the city itself. In large cities where there are subdivisions that can be separately taxed, there is no good reason why this expense should not be imposed upon the territory covered by the plan and assessed directly upon the real estate within its boundaries. What was previously acreage property, unavailable for urban development, at once becomes capable of subdivision into city lots fronting upon officially recognized streets, and there is no single step in its development, not even the physical construction of the streets, which will be of more direct benefit in that the property at once becomes marketable as city lots.

Titles and Surveys. When it is necessary to acquire title by condemnation proceedings to the land within street lines, further and more detailed surveys become necessary in order to determine the precise area to be

taken from each owner and the exact location of buildings which may be taken or damaged. As the cost of such acquisition is commonly assessed upon an area of benefit, the expense of such surveys and maps may be, and frequently is, included in the costs of the proceedings, but it sometimes happens that expensive surveys are required to locate certain lines, while information so obtained will be required in connection with similar proceedings relating to other parts of the same street or to adjacent streets. In such cases it is obviously unfair to impose this special expense upon the property which will be affected only by the particular street. Such work is properly chargeable to general taxation or to the same account from which the cost of the general plan was paid. Finally, there will be the surveys needed for the preparation of the actual contract plans and the cost of engineering and inspection during construction. These are nearly always charged to the fund from which the cost of the actual work is met, whether it is to be paid by the city at large and raised by any of the methods already referred to, or whether it is to be assessed upon the property benefited.

13. Acquisition of Titles

Valuation of Land for Highways. The existing roads in rural districts and the oldest streets in cities, which were once rural highways, have in most cases been created by traffic; they were not laid out in accordance with any plan tho the way for them was often cleared thru forests. Public right in them has been established by user and not as the result of any legal proceedings, and that right is generally an easement for highway purposes and is seldom a fee title. As new highways are acquired or when the old highways are widened or straightened the property is likely to be purchased, in which case a fee title is usually acquired. The state, town or city often exercises its right of eminent domain and condemns the land required thru a commission appointed by the court. Such procedure is necessary in case any part of the cost is to be assessed, as prices fixed by private agreement are likely to be questioned unless the owners who are to receive the awards and those who are to pay the bill have their day in court with an opportunity to make objections. These proceedings are cumbersome and expensive, and the unreasonable time consumed and the enormous costs are frequently the cause of much complaint and often of scandal. Extravagant claims are made as to the value of the land taken, full value for the area within the street lines being insisted upon. It is difficult to understand the mental process by which members of condemnation commissions arrive at their conclusions as to values. When a street plan has been officially adopted and the property has been sold the title is generally given to the center of the street. If the street is 60 ft wide and the abutting lots are laid out to have a depth of 100 ft, the title of the owner covers a total depth of 130 ft, half of which is within the lines of the street. This total area, however, is little more than acreage property and has no value as city lots until the paper street shall have been converted into an actual highway affording access to the lots. To claim city-lot values for the 30-ft strip without which the remainder is not susceptible of use seems absurd, and yet such claims are generally made and too frequently allowed. When the property which is left is not of such size or shape that it can be developed as building plots substantial compensation is equitable and proper, but the average owner of property which is to be condemned is insistent upon large awards for the taking of that

which is of no use to him until it is a public street, and he seems to have no difficulty in securing expert testimony to support his claims.

Buildings within Street Lines. In many instances buildings are erected wholly or partly within the lines of streets for the express purpose of securing large awards for damages after which the buildings or the portions of them which are taken are sold at public auction for a nominal consideration and are usually bought back by the original owner. This practice has been called HOUSE PLANTING, and there are authentic records of cases where, after securing large awards for such buildings and purchasing them back again for a few dollars, they have been deliberately moved to another site held by the same owner and wholly or partly within the lines of an unopened street and the same procedure is repeated. If the building is sufficiently substantial to survive several such moves, a very handsome return can be realized on the original investment. The most effective way to deal with the question of extravagant claims for property taken for street purposes is to assess directly back upon the abutting land the entire cost of the proceedings, in which case the claimants may have the satisfaction of paying their own awards, but this would not remedy the injustice imposed upon other owners as a result of house planting. It is obvious that in case there are not buildings within the street lines it is to the interest of the owners to cede voluntarily the land required for the street without compensation and save thereby the expenses of the proceedings which, when the cost of surveys, the making of the damage maps, and the fees and expenses of the condemnation commission are included, are considerably greater than the aggregate of the awards. In some states an attempt has been made to deal with the evil of the erection of buildings within street lines by the enactment of laws declaring that, after the proper city authorities shall have adopted an official plan showing streets and parks and property which may be taken for any other public purpose, any owner who erects a building within the limits of the land to be taken does so at his own risk and is not entitled to compensation therefor. Such a statute exists in the State of Pennsylvania and, while the constitutionality of such a law may be open to question, it appears to be so obviously in the public interest that it has not been successfully attacked in the Pennsylvania courts. It is true that such a policy may involve grave injustice if the taking of property so preempted is unnecessarily delayed. Any owner of land should have the right to make such use of it as may be proper and legal unless it shall have been taken from him by due process of law. When such owner shall have in good faith shown his intention so to use or improve his property, the city or the state should in justice act with reasonable promptness by taking that which they have declared their intention ultimately to take and pay a fair price for it.

Irregular Property Lines and Unusable Remnants. Where streets are so located with respect to property lines that irregular and unusable remnants will be left which cannot be profitably improved while in single ownership, or when street widenings result in leaving plots too shallow for suitable use, the damages are large and proper compensation must be made. A method of dealing with such cases, which has been strongly recommended of late, is the exercise of the right of excess condemnation when such right exists. This simply means that the state or the city in taking property required for a public use shall not be limited in its taking to the precise lines required in order to carry out the improvement, but that it may take the whole of parcels which may be so mutilated as to in-

volve substantial damage. After the improvement has been carried out the area not needed can be resold at the advanced price which will result from the improvement which has been made. This is really the taking of a part of the unearned increment or the increase in value caused by something which the public has done. It will, of course, require an increase in the capital investment and the power, if granted, should be conservatively used and land speculation for profit should be discouraged. This method has one great practical advantage in that remnants which could not be used in separate ownership, and which, when unimproved, would give the street a ragged and shabby appearance, may, when combined in a single ownership and with the possible addition of enough land to give suitable sites for buildings, become very valuable.

German Method. A method of dealing with the problem presented by very irregular property lines which will not fit a rational street system has been adopted by German cities thru the enactment of a law commonly known as the LEX ADICKES. This statute authorizes the city to take all of these irregular parcels, to lay out a suitable street system including such open spaces as are deemed necessary, and to divide the portion which remains among the original owners in proportion to their former holdings. While the area of each owner may be reduced 25% or more, depending upon the land taken for streets and open spaces, each parcel will be so located with respect to the streets as to be available for suitable development.

14. Grading, Curbing and Sidewalks

Grading New Highways. In creating a system of rural highways the surface improvement and such grading, regrading, straightening and draining as are needed are likely to be carried out at the same time and frequently under a single contract. In the case of a city street where there has been no existing highway, the first step is usually the grading, curbing and laying of sidewalks, while the pavement is commonly deferred until the abutting property is at least partially developed. This will not only allow time for the installation of the ordinary subsurface structures and the settlement of the trenches in which they are placed, but will prevent the mutilation of the new pavement by frequent openings for the ordinary surface connections, and it will also allow the property owners to meet the expense of the completed street in several payments. In cases where the grading is heavy and the cost of the improvement other than pavement is large in comparison with the value of the property, it is often desirable to carry out that part of the work progressively, the street being graded for only a portion of its total width or even to a temporary grade which will furnish a passable road and permit such development of the abutting property as is practicable before the final grade is physically complied with. If such a policy be adopted it is necessary to have a clear understanding that the grade is temporary and not final, and that such buildings as may be erected shall conform with the ultimate grade as officially adopted and that, if they are located with respect to the temporary surface, they will not be entitled to damages when the grading is completed.

Widening and Regrading Established Highways. Streets are frequently laid out to include old highways in use at a lesser width and lying wholly within their lines. The grades of such highways will have been established by user altho they may be entirely unsuited to either the traffic or the drainage of city streets. When the time for grading comes, serious damage will be imposed upon the buildings which may have been erected accord-

ing to the user grades, and such damage must be paid. While easy gradients are necessary on important traffic arteries, instances will be found in most cities where uniform grades have been established and physically carried out on local streets quite well built up, with the result that the houses are left some feet and often a full story below the new surface, while the damage might have been greatly lessened by the adoption of a modified grade which would have served the needs of the particular street. Such a grade may not conform with the ideas of the highway engineer but there are times when economic considerations should be controlling, provided always that a saving in the first cost of construction will not entail a greater subsequent expense or result in conditions prejudicial to the health, convenience or general welfare of the entire locality.

Curbing and Sidewalks. The curbing and sidewalks are usually laid at the expense of the abutting owners; in some cities their repair and renewal are also chargeable against the lot owners, while in others the burden is assumed by the city at large. In the latter case it is obviously in the interest of the owners to lay the cheapest material permitted, while the interest of the public requires that they be made as substantial and durable as possible within reasonable limits of cost. Aside from expense of renewals, where they are imposed upon the city, the public safety and convenience require that such renewals shall not be necessary at frequent intervals. Sidewalks are usually laid by the property owners under special permits and presumably in accordance with standard specifications. In the majority of cases they are put down by speculative builders whose interest in them lasts only until they can sell the houses. While cement walks can be laid far more cheaply than stone flagging, the builder is often disposed to make them even cheaper than is consistent with good workmanship. The cost of the house to the purchaser would be inappreciably affected by the difference between the best and the poorest work of this kind, and it is the duty of the responsible city officers to protect the investor as well as the city from the danger of accident resulting from defective walks and from the cost of replacing them with those that are suitable.

15. Pavements

Original Pavement. The cost of the original or first pavement is generally assessed upon the abutting property. In exceptionally wide streets this would involve so heavy a burden that a portion of the expense is usually placed upon a larger tributary area or is even assumed by the city. Very wide streets with several roadways are often treated as parkways and in such cases one of the roadways, which is designed to accommodate restricted or relatively high-speed traffic, is often paved at general expense. In streets having a width of 80 or 100 ft it is quite likely that there will be surface-railway tracks, and the traction company is usually required to lay and maintain at its own expense the pavement between its tracks and rails and for several feet outside of the outer rails. This will reduce the expense to the abutting owners so that it will be no greater and in some cases will be even less than that of the paving of an ordinary residential street. In some cities the railway companies are required to pay a certain annual sum per mile of single track in lieu of their paving obligation, the city assuming the entire expense of the maintenance of the pavement. Responsibility for the upkeep of pavement is, however, an incentive to substantial track construction which will materially reduce the cost of surface repairs.

Selection of Type of Pavement. Owners of property who are required to pay for the first pavement are disposed to argue that if they are to pay the bills they should have the right to determine the character of the pavement, and if this right is conceded they naturally select the cheapest type which is permitted, especially where they can not be called upon to pay for repaving. This not only involves greater expense to the city at large but it is impossible to carry out a consistent general plan of street paving. A change in the kind of pavement every few blocks is a serious handicap to travel, especially on lines of thru or continuous traffic. While the property owner who is to be assessed is not disposed to concur in this statement, the character of the pavement to be laid on each street should be determined by one who possesses expert knowledge of the kind of surface best adapted to the grades, the probable traffic and the general character of the development of the abutting property. It should not be necessary to wait until the first pavement is worn out and another is to be laid at public expense before a comprehensive paving plan may be realized. There is need of a paving program which shall be consistently carried out regardless of how the cost is to be met, regardless of the whims or projects of the abutting owners, and regardless of the missionary work of promoters of a particular kind of pavement who may have secured signatures to petitions which appear to indicate a decided preference for the type of roadway surface in which they are interested.

Pavement Renewals. While the cost of the renewal of the pavement is usually paid out of general city funds, the expense of maintenance and repairs is always so paid. Public opinion will no longer tolerate the neglect of pavements until they are so worn that travel over them becomes positively dangerous and an entire repaving is the only remedy. When repairs are made as needed and records are properly kept, the annual cost of maintenance is readily ascertained. The time for complete repaving is therefore easily determined and is when the maintenance expense becomes equal to or greater than the interest and sinking fund charges on the cost of a new surface plus the average annual expense of maintaining the new pavement during its life, assuming that the funds required are borrowed for a term of years correspondnig with the estimated life of the pavement which is to be laid. If the loan is for a longer period there may be an apparent reduction in the annual expense of the new pavement which might be held to justify an early replacing when the cost of repairing the old pavement equals or exceeds this sum, but there will, in the case of a long-term loan, be an overlapping of the financing periods which will vitiate such conclusions. The folly of the long-term loan has been so frequently pointed out in the preceding Articles that it will be assumed that it will not be resorted to.

16. Street Widenings

The Widening of Existing Streets constitutes a special and exceedingly difficult problem and the financing of such projects involves both the cost of the acquisition of additional property, the damages incurred by the destruction of buildings, and the physical improvement of the widened street. The cost of acquiring the land for street widenings, including damage to buildings, is commonly made a general city charge, altho in some cases a small portion of the expense is assessed upon an area of benefit. The fact that a widening is necessary is a clear indication that the street has assumed more than local importance, but it may also be assumed that its local importance will be increased to a certain degree by the

widening and, as already pointed out, if there is a local benefit, that benefit should be recognized by some local assessment. The general principles hereafter outlined in Arts. 17 and 18, which should govern the distribution of the expense of acquiring title to a new street, can with justice be applied to the widening of an existing street, with the understanding, however, that the share of the expense imposed upon the restricted local area of benefit, usually the frontage, should relate to the land damage only, while the building damage should be included in the share assumed by the larger district or the city. If, for instance, a street 50 ft in width is to be widened to 80 ft, the frontage assessment should be limited to that portion of the cost of acquiring the 30 ft of additional land represented by the 10 ft necessary to give the street a width of 60 ft and one-fourth of the width in excess of 60 ft, which in this case would be a total of 15 ft or 50% of the land damage, the remaining 50% together with the building damage being placed upon the larger district or districts of benefit. In case a street 50 ft in width were to be widened to 100 ft, the portion of the expense for additional land which should be placed upon the first area of benefit would, under the same theory, correspond with 20 of the 50 ft to be acquired or 40% of the land damage, the building damage, as before, being included in the assessment to be placed upon the larger area of benefit.

Old Irregular Roads Included Within Street Lines. It frequently will happen that in the first platting of a street system an existing highway along which there has been a certain amount of irregular building is to be included in a new highway of greater width. While this would not constitute a widening in the sense above referred to, it is a widening so far as its effect upon the adjacent property is concerned, and in such cases an equitable distribution of the expense will be as follows: For the area within the lines of the old highway it is probable that no awards will be made in view of the public easement. If the old highway was 40 ft wide and the new one is to be 80 ft in width, a separate estimate should be made of the value of the undedicated land to be acquired and another estimate of the building damage. If it were found that the building damage were twice as much as the land damage, this might be considered as equivalent to the acquisition of 80 ft of land in addition to the 40 ft which are to be acquired to give the existing highway a width of 80 ft. There would then be an equated width of 120 ft, and the rule proposed in Art. 18, if applied to this width of 120 ft, would result in placing 62.5% of the total cost, including building damage, upon the restricted local area and the remainder upon the larger district. If this equated width, due to estimated building damage, were added to the total width of the street as laid out, instead of the width of the undedicated portion, the total equated width would be 160 ft, in which case, limiting the total width to be assessed to 80 ft, the proportion of the expense to be locally assessed would be 50%. This method of distributing the cost in such cases is believed to be worthy of serious consideration.

ASSESSMENTS FOR BENEFIT

17. The Theory of Assessments

Local and General Benefit. As intimated in the preceding Articles, the demands upon the resources of the state, and more particularly of the modern city, are so great that in addition to the general taxing power resort must often be had to assessments for benefit whenever possible in order

to meet the cost of improvements where the benefit can properly be considered local. But the theory of assessment for benefit is not that it is something that can be employed when the public funds are required for other purposes where local benefit is not clearly established, but it is founded upon the general principle that where there is local benefit there should always be local assessment. There can be no improvement which has been intelligently planned and executed which will not result in some local benefit and it follows that there should always be some local assessment. No improvement, however small or however large, will be of equal benefit to the entire city, and to distribute the burden of paying for it over the whole city according to taxable values is unfair in that it is not placed according to benefit. The owners of property in the immediate vicinity are frequently enriched at the expense of those whose holdings are entirely outside the district directly affected.

Special Assessment for Local Benefit. The practice of assessing the cost of street or local improvements is probably more general in the United States than in other countries and it is accepted as an equitable and rational plan. In a paper read before the Municipal Engineers of the City of New York in May, 1914, by William C. Ormond, the President of the Board of Assessors, there is a review of the manner in which this policy has been developed, first to a limited extent in England and later and more fully in the United States. One of the earliest statutes which specifically recognized the theory of assessment according to benefit was enacted by the State Legislature of New York in 1787. The courts have repeatedly passed upon the equity and reasonableness of this manner of financing local improvements. A Kansas judge in sustaining the legality of a special assessment said: " There is a justice in this arrangement which commends itself to any right-thinking man, but the injustice of assessing property all over a city for the improvement of a single street must be apparent at a glance." A Mississippi court, while cautioning against the improper use of the power to assess, emphasized the justice of the plan in these words: " I concede that the system of local assessment is liable to abuse, for which reason courts should scrutinize its application with care and also see that an equitable share of the burden should be borne by the public, but it will be readily foreseen that if the whole local charge for local improvements is to be borne by the city treasury, grievous abuses might be practiced upon the inhabitants generally to subserve the local interests of designing men holding property in a particular neighborhood." While the subject under immediate consideration is the financing of highway improvements, the principle of assessment for benefit is capable of a much broader application. While there are certain great projects that are commonly deemed of general interest, there are few which do not involve some special benefit to a particular locality. If a new park is to be created the property in its immediate vicinity will acquire a certain fixed character and its value will be substantially increased. If a new and important public building is to be erected there will be much interest in the selection of the site and, as soon as it is determined, it will have a marked influence upon the property in the neighborhood, and it would not be difficult to give instances where, before the building was completed, the value of the surrounding property has at least doubled, especially if the building is surrounded by considerable open space. If the city were, as some of our great cities now do, to construct a new rapid-transit line bringing hitherto vacant lots within easy reach of its business center, or

if it were to provide a new waterway permitting docks and basins to be created in hitherto inaccessible swamps, the effect upon this suburban land and these useless swamps can be readily foreseen. If the property in the neighborhood of the new park, the new public building, the new transit line or the new waterway is to be increased in value by some act of the city, and if the owners of this property are to be enriched by this act, it is fair and just that these owners should contribute more per unit of assessed value toward the cost of the improvement which is to enrich them than do the owners of other property more slightly, if at all, affected.

18. General and Special Benefits

Local Benefit. In the case of streets that serve a strictly local purpose the benefit may be considered to be entirely local and the entire expense can properly be assessed directly upon the abutting property, but there will be many cases where the benefit will be more than local and will extend to a considerable distance beyond the immediate frontage, while it may even be of substantial service to the entire city or even the metropolitan district. Nor does the relative amount of local or general benefit in all cases depend upon the width of the street which is to be acquired and improved or upon the cost of the improvement. A street 50 ft wide may be of more general use than one 100 ft wide which has been planned to give a distinctive character to the abutting property or to that within a limited district. An improvement costing $100 000 in one part of the city may be more distinctly local in its benefit than one costing $10 000 in another section.

General and Local Benefits Affected by Street Widths. While no definite rule can be adopted to govern the distribution of assessments representing general benefit over the district or the geographical units to be assessed, it should be possible to prescribe a method of determining the amount and extent of local benefit, particularly in the case of new streets and boulevards. Let us assume that 60 ft is the maximum width required for a local street; then the entire cost of acquiring and improving all streets 60 ft or less in width may properly be placed upon the property within a half block on either side of the street. In the case of wider streets that proportion of the cost represented by the ratio which 60 ft plus 25% of the excess over 60 ft bears to the width of the street would probably be an equitable proportion to assess upon the local district. Up to a certain limit, property fronting a wide street is more valuable, and it would be manifestly unfair to adopt a rule which would result in making the cost of acquiring a street 70 or 80 ft wide no greater or possibly less than would have been the cost of a street 60 ft wide. On the other hand, after a street reaches certain proportions, additional width will not involve additional benefit. It may be assumed that a share of the expense which would be equivalent to paying for a street 80 ft wide should represent the limit of local assessment. This limit would be reached under the rule proposed when the street becomes 140 ft wide. The percentages of cost which would be locally assessed would therefore be as follows for various street widths: 60 ft, 100%; 70 ft, 89.3%; 80 ft, 81.25%; 90 ft, 75%; 100 ft, 70%; 120 ft, 62.5%; 150 ft, 53.3%; 200 ft, 40%. This plan of distributing the expense is shown diagramatically in Fig. 1, which also indicates the proportion of the cost which might equitably be placed upon a secondary area of benefit, or upon the entire city in the case of very wide streets. It has been assumed that, beginning when the street exceeds 60 ft in width, the

amount assessed upon the secondary area of benefit will gradually increase with the street width until the latter becomes 140 ft, at and after which the frontage assessment and that on the secondary area will remain respectively at the proportions corresponding with 80 and 20 ft, the remainder of the expense being placed upon the city at large.

Tuttle Plan of Distribution of Assessment. In any case, no rule should be adopted until it has been carefully tested and it has been demonstrated that the assessments levied in accordance with it will constantly decrease with the distance from the improvement. This decrease should not be directly in proportion to the distance but in a geometrical ratio. A curve to determine the distribution of assessment after the limits of the district have been decided has been proposed by Arthur S. Tuttle, Deputy Chief Engineer of the Board of Estimate and Apportionment of the City of New York, in accordance with which about 32.5% of the assessment would be placed upon the first 10% of the distance to the outer limit of the area of benefit, 55% upon the first 25% of the distance, and 80% upon the district extending half way to the boundary of the assessment area (see Fig. 2). The diagram, illustrated in Fig. 2, could also be used to determine the boundary of the district of assessment if it were decided to place a certain percentage of the expense upon the immediate frontage and to distribute the remaining cost over the rest of the district in properly graduated proportions.

Fig. 1. Diagram Showing Proposed Distribution of the Cost of Acquiring Streets of Different Widths Between the Abutting Property and Larger Areas of Benefit

19. Installment Assessments

Payment by Installments. The privilege of paying by installments is given by some cities and this lightens materially the burden of the property owner. Such a policy involves a greater capital investment on the part of the city as there is a much longer period between the time of the first outlay and the return by the payment of the assessments. In small cities it was formerly customary to pay the contractor for street improvements in warrants issued against the owners of the property chargeable with the cost of the work, such warrants being a lien upon the real estate and the contractor being obliged to enforce payment by legal action if he could not otherwise collect the assessments. While these warrants carried interest, the delay and in some cases the legal steps required to make the collections resulted in substantially higher bids, altho the city's financial obligations were lightened. This method has been quite generally abandoned. The city pays for the work as it is done and it is customary to include in the assessment interest on all payments from the date of the disbursement to the time of the confirmation of the assessment

roll or to such a date subsequent thereto as will allow time for proper notice that the amount levied against each piece of property is due. After a reasonable time in which to make the payments the assessments become arrears and a higher rate of interest is charged until they are paid, and in many cities no payments are accepted except for the full amount of the assessment.

Benefits of Installment Plan. When the amount of the assessment is a substantial proportion of the actual value of the property it is exceedingly difficult for some of the owners to discharge the obligation in a single payment, and in order to lighten the burden the right to pay in five or ten annual installments is sometimes granted when the amount of the assessment exceeds a certain percentage of the value of the property as assessed for purposes of taxation, this percentage varying from 10% to as low as 3%. The value considered should, of course, be that of the land exclusive of buildings in order that property owners who have added to taxable values by the erection of buildings should not be discriminated against. Interest on installments is usually charged at the rate of 5 or 6% from the time of the levying of the assessment until they are paid, such interest on all unpaid installments being due and payable with each installment.

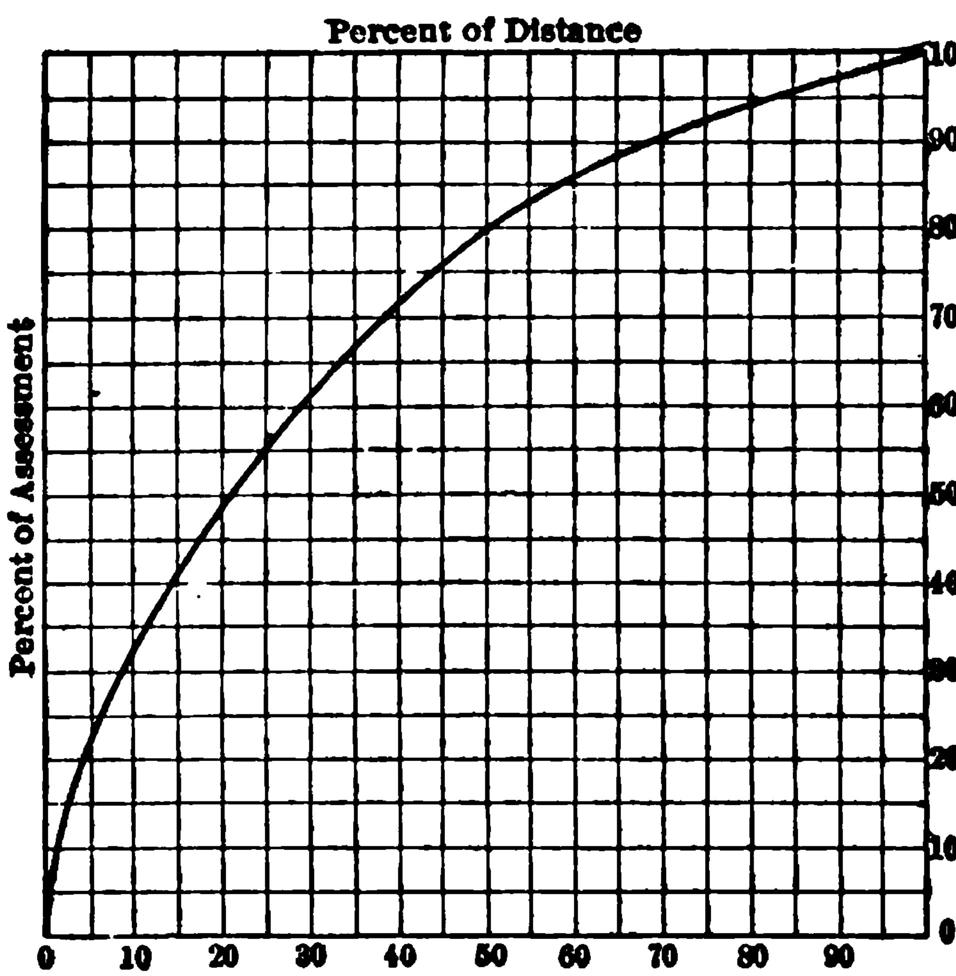

Fig. 2. Diagram Showing a Method of Grading Assessments for Benefit According to the Distance from the Street to be Acquired

European Practice. In European cities the rate of interest which is charged is often very small, in some cases as low as 2%, but in some of these cities, especially in Germany, there are large amounts of capital available for this purpose, the result, often, of real estate operations in which the cities may engage or the result of profits from the operation of the public utilities which are generally owned and operated by the municipalities. This does not mean that in German cities it is easier for the owner of a modest home to secure and pay for his street improvements, as there are other regulations which make it very difficult, if not impossible, for him to do so. It is a common practice, for instance, to refuse to permit the owner of a plot to erect a building until the street upon which it fronts shall have been entirely improved with curbing and pavement connecting with another street or a part of the same street which has already been so improved. The result of this policy is that the built-up parts of the

city grow solidly outward with no vacant spaces and no unimproved streets intervening between the older and the newer portions. Another result is that street improvements and building operations are generally undertaken only by corporations, such as banks and realty companies, having abundant capital. The practice of allowing assessments to be paid in installments appears, therefore, to prevail to the greatest extent and on the most liberal terms under conditions where that privilege is not most needed, or, at least, where it cannot be availed of by those who need it most.

20. Deferred Benefits

Potential and Immediate Benefits from Improvements. Benefit results from street improvements in all cases, but in many instances it is a potential rather than an immediate benefit. If the owner of the property is prepared to improve his holdings at once in order that they will bring him some return the benefit is realized. If he has not the means to develop it, his capital investment is increased by the amount of the assessment but will bring him no immediate return. If the property is already built upon the benefit is immediate and is at once reflected in an increased rental value, or more livable conditions or better business conditions if he occupies it himself. In the great majority of cases the abutting property is unimproved and unproductive at the time the street improvement is made and the improvement is asked for in order that it may become productive or marketable. But a long delay often ensues before the owners, or at least some of them, are able to take advantage of the bettered conditions resulting from the grading or paving of the street.

German Method. To meet such conditions some cities recognize the fact that the benefit is deferred and, while the city may advance the money, the assessment is not payable and does not become a lien upon the property until it is improved in such a manner that the benefit ceases to be merely potential and becomes actual, a low rate of interest being charged for the period between the initial expenditure and the imposition of the assessment. This also is distinctively a German policy. Its great advantages to the property owner are obvious but it also greatly increases the amount of the municipal funds which are diverted from other purposes. The advantages, as in the case of installment assessments and under the restrictions noted in the preceding article, are enjoyed by the corporations which can undertake improvements on a large scale, and seldom extend to the small individual property owner or purchaser unless the corporation making the development gives him the advantage of the generous treatment it has received. Under the system of governmental control and regulation which generally prevails in Continental Europe such a share in the advantages of the system are likely to be insured to him.

Unused Sources of Revenue. In the United States such methods of financing local improvements have not been attempted owing to the extensive demands which are made upon the resources of cities for other purposes. It is only lately that the cities have begun to avail themselves of sources of revenue other than those derived from the taxation of real estate. Franchises in perpetuity to use the public streets at, above or beneath the surface were formerly given away without substantial compensation. The Federal, State and Municipal Governments have but lately awakened to the necessity of conserving and developing their resources in such a manner as to derive an income from them. They have not been disposed to attempt to render service which it has been argued can be more efficiently and more

economically furnished by private corporations, and they are still reluctant to do so. The size of vehicles using the streets has increased until traffic is seriously obstructed and, while loads have increased until the pavements and their foundations are seriously damaged, no steps have been taken to derive a revenue by the imposition of a special tax upon vehicles of excessive size or upon excessive wheel loads. The widening of the roadways to accommodate larger vehicles and the replacing of pavements broken down by heavy loads involve large additional expenditures, while the cost of administration is constantly increasing and almost the entire burden falls upon real estate. Upon this same real estate must be imposed the cost of street improvements thru the medium of special assessments. The burden is a heavy one and some of the methods of relief which have been outlined in this and the preceding Article, while admittedly desirable, cannot be adopted until some other means are devised for providing revenues in addition to the taxation of real estate.

SECTION 29

ORGANIZATION AND ADMINISTRATION OF HIGHWAY DEPARTMENTS

BY

WILLIAM H. CONNELL

ENGINEERING EXECUTIVE, DAY AND ZIMMERMANN, PHILADELPHIA

ORGANIZATION

1. General Considerations Relative to Organizations

The Essential Prerequisites of an Efficient Highway Engineering Organization has not been given proper recognition in many localities in the United States. The fault lies partly with the engineer and not entirely with the politician, who frequently is blamed for this state of affairs. The average so-called organization politician of the leader type is in many cases a man who interests himself in public affairs for a financial return; he makes a business of politics and lives by it. It is natural that any public work not generally recognized by laymen to be distinctly engineering work would not be regarded as such by the politician, whose desire is to provide as many places as possible for his associate political workers, among whom few engineers are found. The responsibility for this state of affairs, therefore, rests in a measure with the engineer, since the engineering profession as a whole has regarded the highway problem too lightly and has not been sufficiently jealous of the infringement upon its rights, namely, to supervise all work, public or private, that is of an engineering nature. The doctors

and lawyers have to build up safeguards to protect what they consider their prerogatives. You never find an engineer supervising or conducting work coming under the jurisdiction of either one of these professions, but there are innumerable cases of lawyers and business men placed at the head of highway departments, the excuse being that they are executives. Nevertheless, this is engineering work, and while one of the principal requisites for such a position is executive ability, engineering knowledge is equally important, and the real qualification essential for the directing head to successfully conduct such a department is engineering executive ability, not executive ability engineered by a business man or a lawyer, such as we have been having in many of our state, municipal, county and town highway departments.

Responsibility of the Highway Engineer. Business concerns must advertise their goods, not only for the purpose of encouraging sales but for the protection of the public, as well as for self-protection; they must call attention to any imitations that will not answer the purpose or bring about the desired results. Likewise, it is the duty of the engineering profession to educate the public to get a dollar's worth for a dollar of expenditure, whether it relates to public or private work, so long as it is engineering work, by employing competent engineers to supervise highway and other engineering work. This means engineers to plan, organize, and operate all highway departments. In other words, a proper highway engineering organization does not mean engineers working under the direction of a lawyer or business man commissioner, but an engineering organization from top to bottom, with an engineer heading the organization, no matter what the title may be. This principle is an important one and should be ever before the engineer. He should be brought to consider seriously the prerogatives and functions rightfully belonging to members of his profession, organization work, executive ability, business management. The outlines of highway engineering organizations that will follow are based on the principle that there will be a single executive in charge who shall be a highway engineer.

2. Fundamental Principles Underlying Highway Organizations

A Definition of Organization, with particular reference to highway work, follows: The combination of correlated integral parts into a whole to systematize and simplify the operation, and bring about a maximum of efficiency in the service rendered with a minimum of friction. Using this definition as a guide and common sense principles in its application to organization or reorganization work, the ground work will embody the fundamental principles of organization. The carrying out of these principles involves a detailed study of the functions coming under the jurisdiction of the organization and their relation to one another. The combination of the correlated integral parts into a whole should constitute a logical arrangement of the principal functions of the organization and not an arrangement to suit the personnel, unless it is only temporary and necessitated thru force of circumstances. This point is brought out because there are so many instances where certain functions of an organization are grouped for the purpose of putting them under the jurisdiction of an individual who is qualified to handle the work. This is contrary to the fundamental principle of organization, and is the poorest kind of logic. The organization should be planned and the work systematized in such a manner that it will not be dependent upon any individual. The old idea of carrying your organization in your hat is exploded and generally considered to be the greatest enemy of sound business engineering

management for all classes of public works. Unfortunately, however, many departments are still run along such lines, the officials forgetting that it is not their business but the public's business, and that their occupancy of office is only temporary, while the business must go on forever, which makes it perfectly obvious that the organization should be planned in such a manner that it will not be dependent upon them. This does not mean, of course, that a poor selection of division heads will not result in the machinery running down or becoming somewhat rusty. In order that the organization may operate on an efficient basis, it must be properly guided, and right ' ere attention is called to the fact that the human element is a most important one. To control and operate an organization in an efficient and economical manner, it is not only necessary that those in charge of the different functions know how the work should be done, but they must have the good will of their men. It is only in this way that a maximum of efficiency can be brought about in the service rendered with a minimum of friction.

Controlling Factors of Highway Engineering Organizations. The controlling factors in organizing any highway engineering department come under the headings of preliminary studies and organization of an operating department, and include under preliminary studies, (1) scope and character of work, (2) area under control, (3) population and how apportioned; and under organization of an operating department, (1) planning of the organization, (2) selection of the personnel, (3) administrative control, (4) division of responsibility, (5) systematizing the work. The general principles involved in these headings apply to any highway engineering organization, and in order that a logical solution of the problem may be presented, each one of these controlling factors will now be considered.

3. Scope and Character of Work of Organizations

All work relating to public property between the boundaries of highways should come under the jurisdiction of the highway department, whether it be a state, municipal, county or town department.

Municipal Highway Department. The work that should come directly under the control of such a department is as follows:

1. The design of all work pertaining to the highways, including parkways, park drives and small highway bridges.
2. All engineering work relative to lines, grades, inspection of construction, etc.
3. The construction and maintenance of all highways, including streets, roads, parkways, park drives, etc.
4. The control of subsurface structures and encroachments, including all underground conduits, pipe lines, service connections, vaults, steps, street signs, stands, etc.
5. Permits and licenses for vehicles of all kinds.
6. Street cleaning and snow removal.
7. Collection and disposal of ashes, rubbish and garbage.

State Highway Department. The state, while not having the variety of activities, may have as many or more subdivisions of the organization, due to the larger area under control. These activities may be as follows:

1. Planning of route layout and design of all work pertaining to the system of state roads, and county and township roads, including parkways, park drives and highway bridges under state aid.
2. The control of all engineering work relative to lines, grades, inspection of construction, etc.

3. The construction and maintenance of all highways, including those constructed or reconstructed under state aid.
4. The placing of subsurface structures and encroachments, on or under all roads under state control.
5. Permits and licenses for vehicles of all kinds.
6. Enforcement of traffic regulations.
7. Street cleaning, usually snow removal on roads under state control.

County and Township Highway Departments should have control of the same activities for highways under their control as outlined for state highway departments. State laws may, however, as in the case of traffic regulations, give jurisdiction over certain activities to a state department. In some cases, a township or even a county may have charge of one of the usual activities under the control of municipal departments, namely, the collection and disposal of ashes, rubbish and garbage.

4. Area Under Control of Organizations and Distribution of Population

Area under Control. It is obvious that in so far as it is possible all the work should be controlled and operated from one central office. This principle, however, in its narrow sense can only apply to situations where there is a small area under control, such as in a small city or township. As the area increases, the responsibility for carrying on the work must be delegated and while primarily under the control of the central office, the actual operations must be under the control of subdivisions of the organization. For example, in a state highway department, the construction and maintenance work will necessarily have to be carried on under a number of subdivisions of the department. The layout of the routes and planning of the work drawing of specifications, advertising the contracts, etc, however, should be carried on in the central office. Likewise, as the area increases the personal touch with the engineers and employees engaged in supervising the work becomes increasingly difficult and makes it more important to keep the organization machinery well greased so that the operations will run along smoothly, and not only will construction work be carried on to the best advantage, but the details of the maintenance will be given the attention they should receive.

The Population and How Apportioned, is one of the controlling factors in connection with the layout of the system of highways. The distribution of the mileage of highways thruout a system will materially affect the location and personnel of the division organizations.

5. Planning the Organization

It is only necessary to glance over the scope and character of the work coming under the jurisdiction of a large highway department to become convinced of the fact, that no matter how able the personnel may be, ease of operation and economy and efficiency in controlling the different branches of work will vary with the character of organization under which the department is operating. The ideal organization is the one under which it is possible to accomplish results in the most efficient and economical manner and along the lines of least resistance. The perfecting of such an organization is the real problem and grows in importance, depending upon the number of activities, volume of work, and area under control coming under the jurisdiction of the department. The fundamental principles in-

volved in the planning and operating of a successful organization are the same, whether it be a state, municipal, county or town highway department, tho the activities are of a somewhat different nature. The difficulties to be surmounted depend largely on whether the project consists of planning an organization for a new department or, which is more often the case, the reorganization of an existing department. The latter is the far more

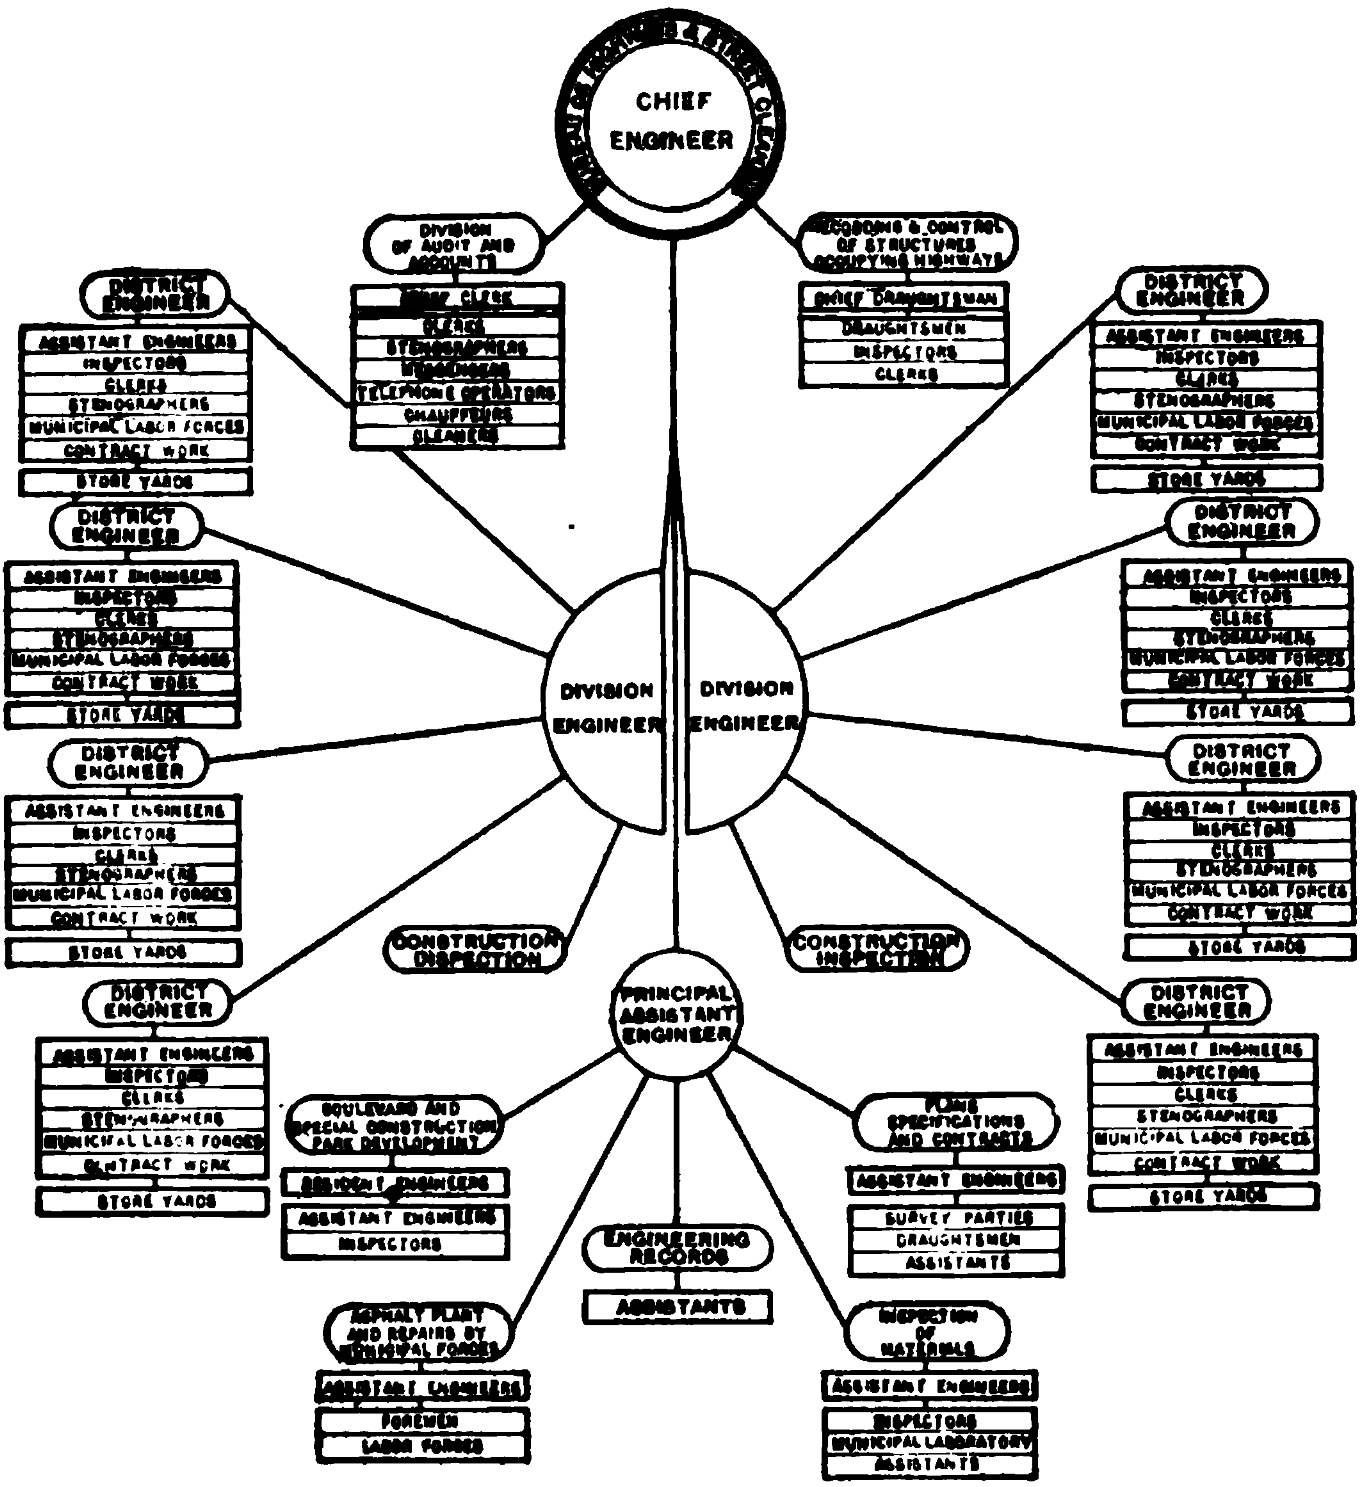

Fig. 1. Organization of a Modern Highway Department

intricate problem, and one that will be outlined with reference to a large municipal department in an endeavor to define some of the principles involved and the difficulties to be overcome.

After having completed the PRELIMINARY STUDIES, the next step is to proceed with the plan under which the department is to operate. This must be done with a view to the future, having in mind the passage of the necessary legislation to put the department on a thoro business basis, and still must be sufficiently elastic to cope with existing conditions, as most of the operations coming under the jurisdiction of a highway department

are of such a nature that they should not be put aside pending proposed legislation, or investigations with a view to a reorganization of the department. It is far better to turn the work out under what might not be an ideal organization, using the necessary safeguards to see that it is properly done, than to hold up the work, not only to the great inconvenience of the public but with a resultant financial loss thru interest charges on appropriations already made, and depreciation on existing plant, to say nothing of the loss due to carrying the overhead charges, and the deterioration of roads and pavements thru lack of maintenance. Reorganization to be constructive

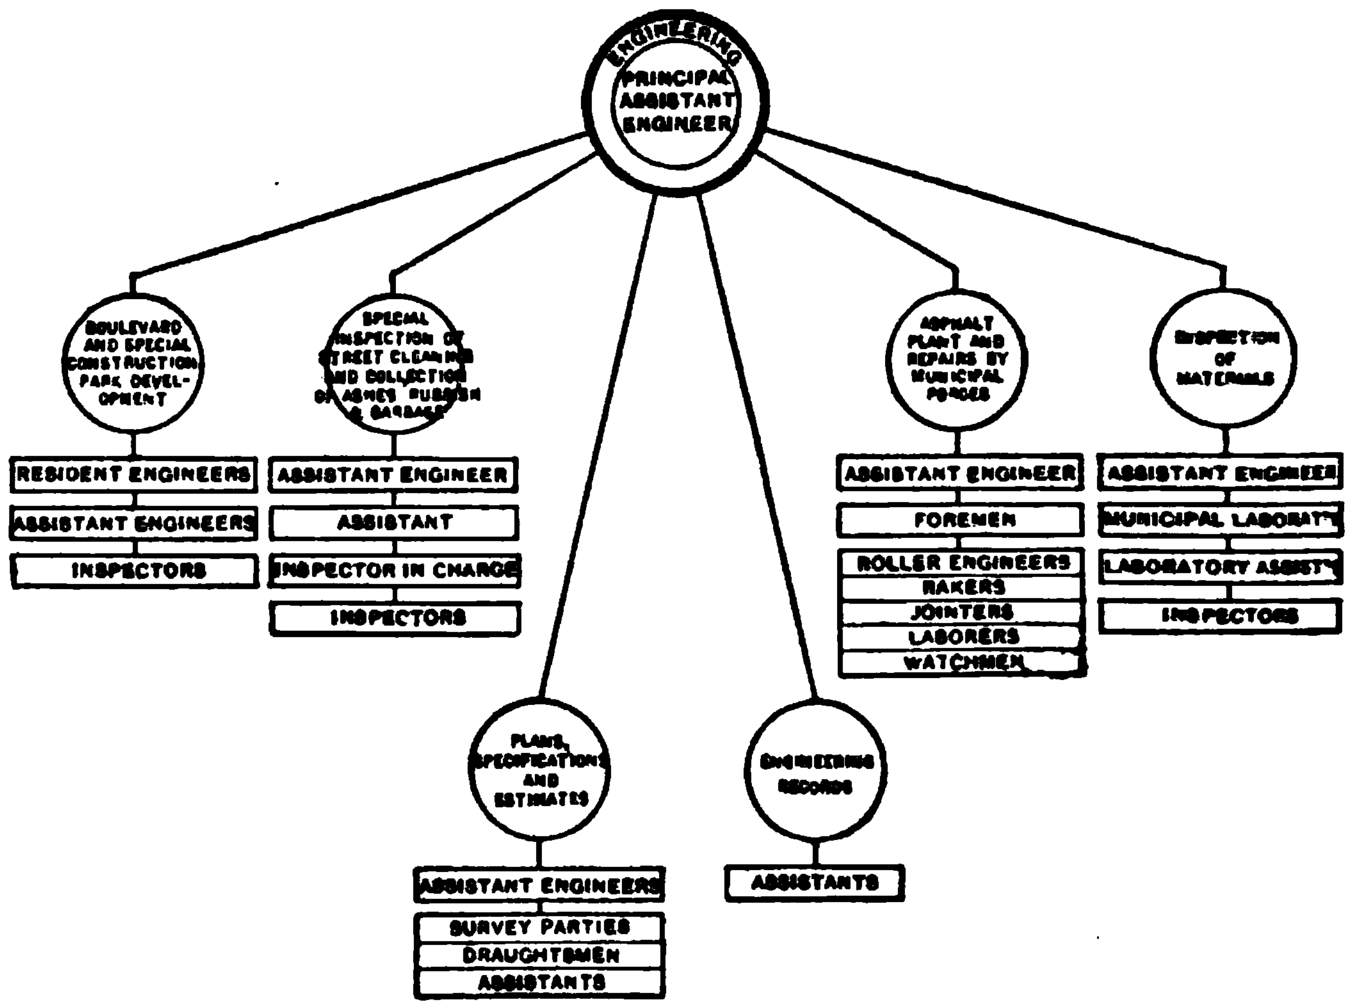

Fig. 2. Organization Chart of the Functions under the Jurisdiction of the Principal Assistant Engineer

must be brought about gradually. The primary consideration in the planning should be to centralize the control of the work, not only as relating to the head of the department, but this principle should be carried right down thru the organization. This means grouping the activities and combining them as far as is practicable, so that not only will the head of the department be familiar with all the activities, but the entire supervising force will be trained to direct all branches of the work. This will do away with shifting responsibility which is so often the case where the maintenance, construction and street cleaning work are under separate divisions, and will tend to make the organization a more stable and lasting one, as the entire force will be working as a unit, and being familiar with all branches of the work, each and every one will have an equal opportunity to advance.

For examples of organizations based on centralized control, see Figs. 1 to 5 inc. The organization chart of Fig. 1 is for a large highway municipal department; and charts, Figs. 2, 3 and 4, for the subdivisions of this same department, as will be seen by making a study of the chart for the general

organization. The organization shown in Fig. 5 has been recommended for a large state highway department, see (17). The fundamental principle set forth in these organization charts is to emphasize the importance of the principle of centralization of control and the delegation of responsibility to different subdivisions in the organization. These charts can be very readily worked into shape for use in any state, municipal, county or township department by making the necessary changes to suit the different character of work and titles of the subdivisions of these organizations.

Selection of Personnel. The personnel other than those of the clerical, stenographic, audit and accounts, and purchasing divisions, should be men of

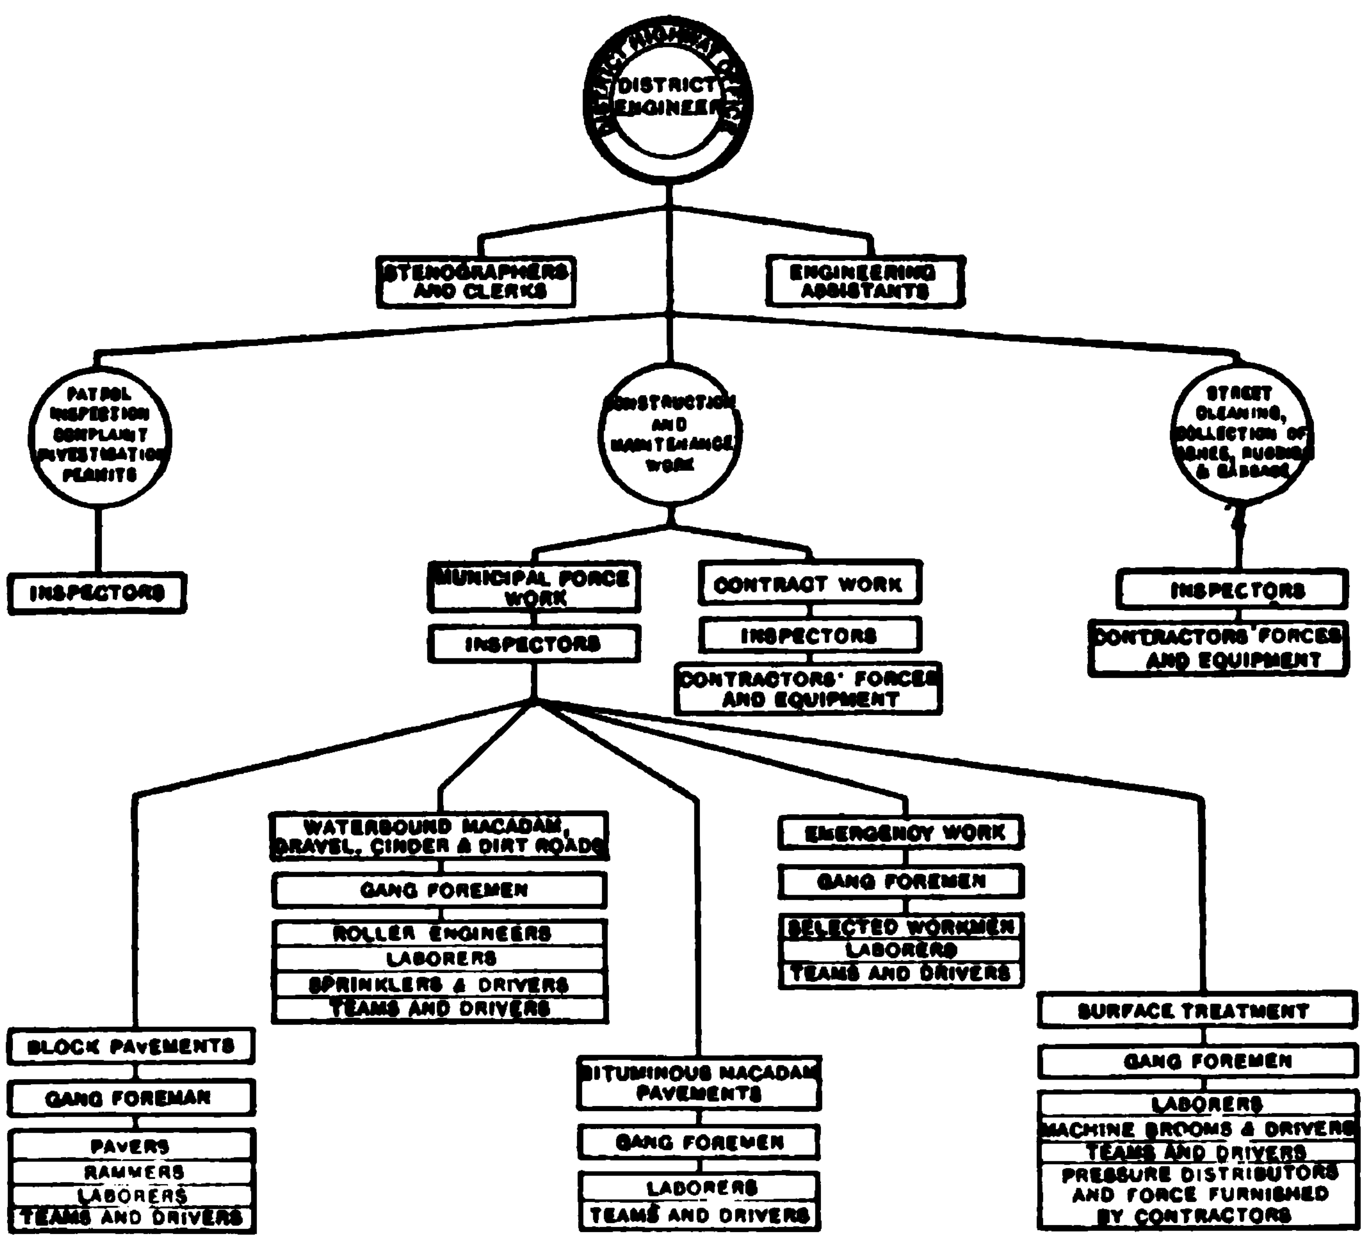

Fig. 8. Organization Chart of a District Highway Force

technical training and experienced in highway engineering, with the exception of the grade of inspector, where a man experienced in highway construction would be qualified. The entire force should be graded in such a manner that the organization will be well balanced. There should not be too many nor too few of the employees in the lower, medium or higher grades, but a proportionate number in each, depending upon the amount and character of work involved. The clerical, stenographic, audit and accounts, and purchasing divisions, as a general rule, remain constant all the year around, while the engineering force necessarily varies with the weather conditions or working season.

Inspectors. In most cases, the temporary inspection force should con-

sist of men who have had practical experience in highway construction, such as foremen, pavers, etc, or in some instances college graduates or students who make a practice of working during the summer months and who have had practical experience in highway work, as a green inspector will usually do more harm than good. The pay for these inspectors should range from about seventy-five to one hundred dollars per month. Ordinarily, during the working season, this force will constitute a large percentage of the entire organization, and it is obvious that those engaged in the inspection of construction work cannot as a general rule be carried during the winter months or when the work has shut down, as their services would not be required. There are, of course, cases where these men might be employed in some other class of work under the state, municipal, county or township government, and if such a thing can be arranged, it is very desirable, as

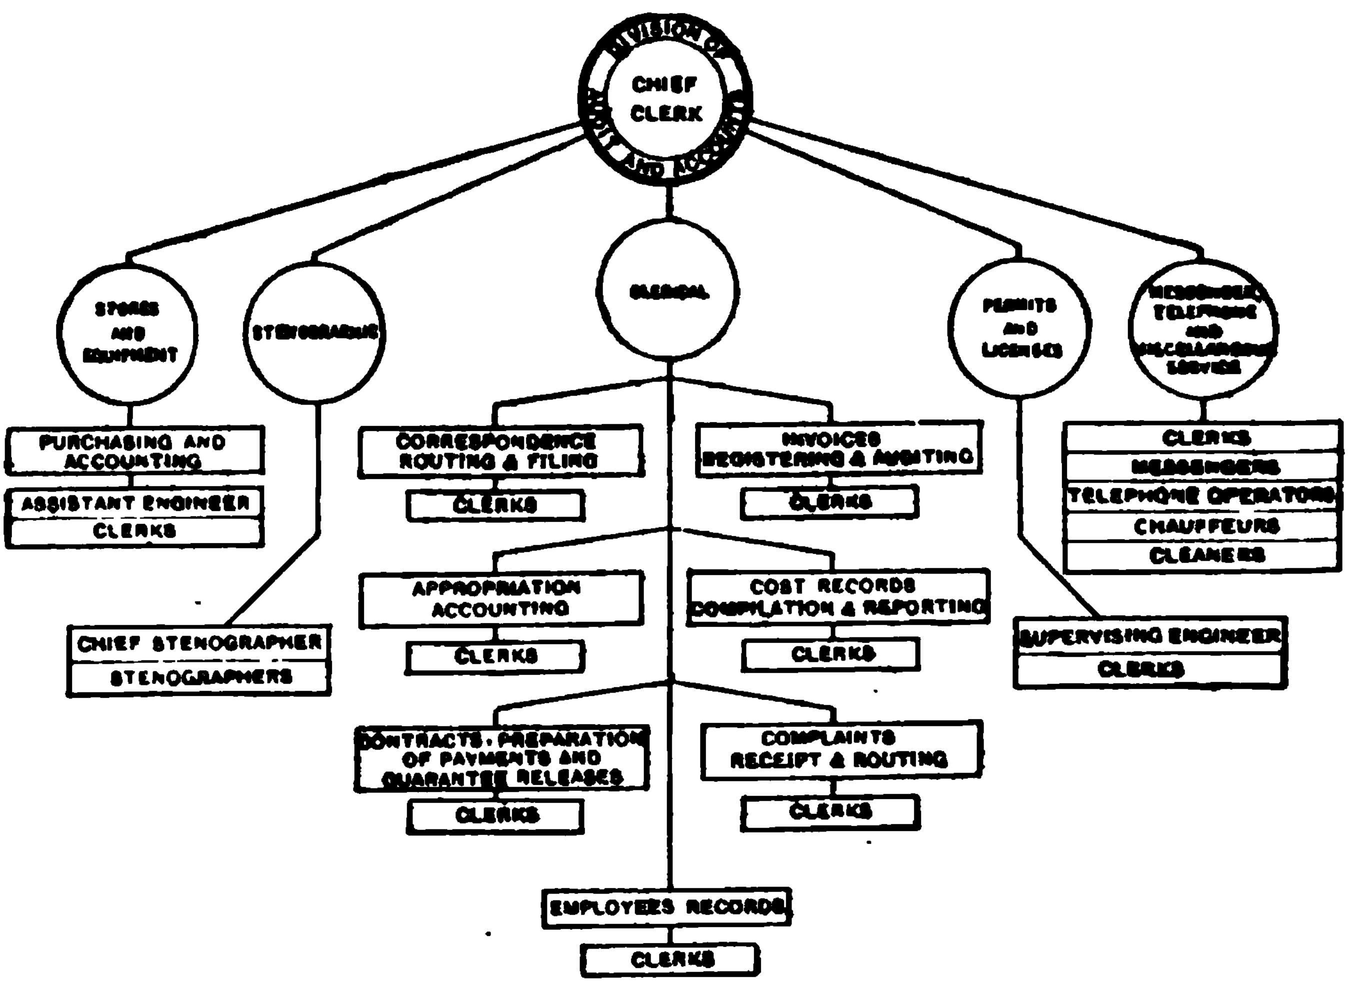

Fig. 4. Organization Chart for a Division of Audit and Accounts

the services rendered by persons regularly employed are superior to those of persons only temporarily engaged.

Effect of Civil Service Regulations. In large organizations the selection of the personnel is one of the most important factors, and, in many localities, is becoming one of the most difficult problems, due to the methods employed by some of the civil service commissions in determining the qualifications requisite for the selection of candidates for the higher positions where personality, broad experience in controlling work and good, sound business judgment should be the primary considerations. These qualifications are recognized to be essential for division heads in whom great responsibility is centered and on whom the success of the organization largely depends, and it is obvious that the selections in these cases should be left somewhat to the judgment of the head of the department, who is held responsible for the work, rather than to the judgment of a

civil service board or thru open competition in a technical examination. Civil service was intended to safeguard the interests of the public and to do away with the SPOILS SYSTEM but the principle of civil service should be construed in a sufficiently broad manner to permit heads of departments to command control of the work, and this can only be done thru a broad application of the civil service laws with regard to the selection of division heads in a large department. Considerable stress is laid on this point as the responsibility of the planning and success of the organization or reorganization in a highway or any other department, rests largely with the head of the department. It is, therefore, obvious that his judgment should

Fig. 5. State Highway Organization Recommended by Blanchard and Hubbard, Advisory Highway Board of N. Y. State Dept. of Efficiency and Economy (17)

carry some weight in the selection of his principal aides on whom he is dependent, as no matter how correct the planning may be to carry on and control the work, the ultimate success will depend largely upon the personality and judgment of these men.

The Qualifications Necessary to Make a Successful Division Head vary with the scope and character of work coming under the jurisdiction of the organization. Just because a man is a good highway engineer does not mean that he will be a success. Personality and business judgment carry just as much weight as engineering ability. The right type of man for such a position must not be lacking in imagination and should possess

the faculty of not only being a natural leader and commanding the respect of his subordinates, but he should also have their good will and this means that he must establish a sort of *esprit de corps* in the organization. A man who operates thru the good will of his subordinates accomplishes far more than the stern disciplinarian who lacks their good will and is feared by them. This is especially true in government, state or municipal work, where the civil service laws and other considerations minimize the authority of the department heads.

In Counties and Townships as a rule the situation is quite the reverse of that where the civil service is administered along narrow lines, and very often men who are entirely lacking in the proper qualifications are selected to control and supervise highway work, purely for political reasons. In some instances, the authorities believe they have the necessary qualifications because they knew something of the practical side of road building in the days before this work was revolutionized thru the advent of the automobile. This type of man usually adheres to the old methods and is too set in his ways to change. In these days every county and township should have the advice of highway engineers, and if this is universally done, many millions of dollars will be saved to the taxpayers. In every case an engineer should be in charge, and the responsibility for the selection of methods of construction and types of pavement should rest with him, and the local authorities should bow to his judgment in such matters; his assistants should also be engineers or men experienced in road construction. The selection of the personnel for counties and townships is relatively just as important as for a city or state, and as is the case in all matters pertaining to a highway engineering organization, the general principles enumerated here, with reference to the selection of the personnel, are applicable to state, municipality, county and township.

ADMINISTRATION

6. Administrative Control of Highway Work

The administrative control of a highway department is dependent upon a proper arrangement of the functions of the organization in their relation to one another, operating under a thoroly systematized procedure designed to bring about a maximum of economy and efficiency with a minimum of friction in conducting the work of the department. The administrative officers should act in an advisory capacity in connection with the work coming under the jurisdiction of the department and should show tact, initiative and judgment in the management of the organization and in dealing with the public, other departments and legislative bodies. This phase of the administrative control is what might be termed the business executive side of highway engineering and the same principles should govern this work as are in vogue in up-to-date business and public service corporations.

The administrative control should be vested in ONE MAN, and, whatever his title may be, he should be a highway engineer with executive ability and versed in the principles of management. If the department be a large municipal or state department, it is particularly desirable that he should have had experience in the management and control of similar work where his training was not only in engineering, but embraced experience in the executive management of a large organization. This is simply going on the principle that from an administrative standpoint better and quicker results

can be accomplished by the selection of a man with previous experience than one who might have ability but who is not familiar with the work, and who would necessarily have to spend two or three years studying conditions before formulating his organization.

Disadvantages of Commissions. It is a great mistake to put this work under a commission of three, five or more men, as is the case in many states, counties and townships. In municipal departments there is hardly a commission controlling highway work, and the only reason that such a situation exists with reference to the state, county or township work is because these departments are newer and in many localities more of a political than a business undertaking. It is perfectly obvious that better results can be accomplished, and much quicker, by a single administrative head than thru a commission, and in this connection particular attention is called to the undesirability of having large boards of highway commissioners controlling the work of the townships.

The ADMINISTRATIVE FUNCTIONS embody general supervision over the appropriations and expenditures of the department. It is the executive's first duty to see that the appropriations are expended wisely and in an efficient and economical manner. He should also see that the public are kept informed of the manner in which the moneys are expended and the work is being carried on. It is also his duty and one of the administrative functions to see that the employees of the department are properly cared for and receive full recognition for their services. He must give constant attention to bringing about a spirit of coöperation among the employees. No organization will be as efficient as it should be unless there has been established a sort of *esprit de corps* among the employees. This is just as important as any other part of the work coming under the head of administrative control. It is also just as necessary to accord courteous treatment to the public, no matter what the source of their complaint or inquiry may be, in public business as it is in private business. Every communication should be answered fully and completely, and in this way the people will be given an insight into the public business and more readily appreciate the necessity of conducting it on a business basis. One of the administrative functions is to see that every employee is instructed to and does accord courteous treatment to everyone with whom he has any dealings.

Division of Responsibility. There is nothing more important in any organization than to fix the responsibility for the work coming under the supervision of the different functions of the organization. This does not mean it should be fixed only in so far as the head of the department or division and subdivision heads are concerned, but it should be passed right down the line so that each and every employee will bear his share. Therefore the proper arrangement of the division of responsibility for the work is one of the principal factors in any organization, as no matter how well the work may be systematized and how perfect may be the procedure, it will fail to accomplish its purpose unless each and every one of the employees is trained to accept responsibility for his part of the work.

7. Administration of Maintenance Work

General Considerations. Admitting that every department is more or less dependent upon a good organization, the condition affecting the operation and control of a large municipal, state, county or township highway department will be briefly analyzed. The greater part of the work coming under the jurisdiction of such a department, no matter how large or how small,

is or eventually will be, maintenance. Therefore, the success from this standpoint is probably four-fifths dependent upon the organization. It is not intended to underestimate the necessity for a good organization to handle the construction, but this work is of a somewhat definite character and there are more or less well defined principles that can be followed both from the standpoint of the office and field, while the maintenance work coming under the jurisdiction of a modern highway department, which usually embraces all branches of work that is logically highway work, or the care and control of the highways within the right-of-way, is an indefinite quantity. It is practically impossible to continuously and systematically maintain pavements and roads in first-class condition in an economical manner, without a good working organization built up along the lines best adapted to cope with the conditions involved in this important branch of work coming under the jurisdiction of a highway department.

Inadvisability of Separate Maintenance Division. It is not purposed to give the impression that the maintenance organization should be separated from the construction, as separate organizations are apt to result in an overlapping of jurisdiction and a tendency to shift responsibility, and open up a field for unlimited excuses as to whether the construction or maintenance division is responsible for any unsatisfactory conditions that may arise relative to the pavements. Furthermore, it is obvious that the logical organization to maintain the pavements is the one that saw them laid and is familiar with every detail of the construction, as very often a knowledge of apparently trivial conditions in connection with the construction bears an important part in the future maintenance.

The human element is also a most important factor in this question. Human beings are subject to influences, not only in so far as they affect the individual, but collectively, and there are conditions that will influence an organization striving to attain a purpose, to fall short of its accomplishment; as, for instance, where the construction organization is not charged with the responsibility of the maintenance, there is bound to be a subtle influence working, which, in a measure, will result in the construction division taking little or no active interest in a pavement after it has completed its work. This method of handling the work is not the best way to train engineers, as it limits their responsibility by cutting it off just when the opportunity presents itself to protect and care for what they have built, consequently their interest is bound to cease to a certain degree, and the organization loses that intimate knowledge of all the little details of the construction which play such an important part in future maintenance. It is the intimate knowledge of the details of both construction and maintenance, not considered separately but in their relation to one another, that is so desirable as a future guide in highway engineering, consequently the combination of the two organizations in one will accomplish far better results than they would working more or less independently, each with a limited responsibility. Highway engineering may be considered a specialty, but further specializing in construction and maintenance is not logical as the two are dove-tailed and cannot be considered separately. Every engineer engaged in highway work appreciates the fact that there is no such thing as a permanent pavement for either city streets or country roads, consequently, in addition to the cost of construction, the maintenance repair charges during its life must be included in the final cost and is a most important factor in the selection of a pavement. Therefore, it will be understood that any reference made to the organization of the department refers

to the one organization controlling all branches of the work, in a state, municipal, county or township department, even including street cleaning, which is a part of the maintenance work that should come under the jurisdiction of the highway department. The organization is assumed to be so constructed and operated that practically every member of the supervising force will be trained to supervise all the branches of the work and in this way the employees will become much more valuable to the department.

The activities coming under the jurisdiction of the municipal, county, township and state highway departments are not similar in every respect, but the principal functions do not differ sufficiently to affect the problem in the main. A large municipal department embracing street cleaning, collection and disposal of ashes, garbage and rubbish, and snow removal, together with the general problems, such as construction and maintenance of pavements, etc, embraces a greater variety of work than does a state department but principally of a nature that is essentially maintenance work. Likewise in a large state department, with an organization controlling a large area of improved highways, the maintenance problem is more involved and complicated than in county, township or state department with a less mileage of pavements or roads under its care, so that the perplexity of the problem increases not only with the number and variety of activities, but with the area of the territory and the mileage of roads and pavements coming under the jurisdiction of the department. It is, of course, a much simpler matter to cope with this problem where the work involved is such that it can be controlled from a central office, without delegating the responsibility to divisions and subdivisions of the organization. This is especially true in maintenance work, as there is always a tendency among engineers to be lax in attention to details of an apparently simple and routine nature. They are apt to overlook the fact that it is not difficult to construct a pavement as in supervising this work they are simply following more or less standard and well defined principles, where, in maintenance work, there is no set specification to follow, the success depending upon attention, to a certain degree, to daily routine and principally to petty details that present themselves in the actual physical work, and in this there is an unlimited field for initiative. The difficulty of impressing upon the supervising force the importance of close personal attention to detail in connection with the care of the pavements is one of the most important factors in the operation of a large highway department, and must be reckoned with and especially in these times, when the public is becoming more and more exacting and virtually demanding that the roads and pavements be kept continuously in good repair.

For convenience the different branches of maintenance work will be grouped under the following classifications: (1) Routine maintenance; (2) general maintenance; (3) emergency maintenance. For illustration, there will be considered only the more important functions under these classifications.

Routine Maintenance. This includes the cleaning of streets and this branch of work involves an enormous amount of petty detail that is only definite in character in so far as the schedule of cleaning is concerned, which usually calls for a general cleaning for each particular street every so often. The amount and character of cleaning, of course, is largely dependent upon the traffic, type of pavement, and density of population. Therefore, relatively speaking, from the standpoint of the state or county highway department, this problem is a comparatively simple one, consisting primarily of the cleaning of country roads, which work embraces scraping of the shoulders and keeping the gutters open. The magnitude of the problem

varies with the area to be covered and the density of population in a given area; from a more or less simple one on a given country road, it looms up into a very important one in a state highway department, and likewise, from the cleaning of a given street in a small town, it looms up into one of the most important problems in a large municipality; and both with regard to the state and municipal highway department it is largely a question of organization. Once the organization is perfected from an administrative standpoint, the work is two-thirds completed. The main problem in routine maintenance of this character is to organize a working force capable of performing the work along the lines of least resistance in an efficient and economical manner.

General Maintenance. This includes street repair work which is of a distinctly variable quantity and unlike routine maintenance must be coped with by an organization of an entirely different kind from that for street cleaning, which organization consists of a regular working force employed all year round and of a more or less military character. The street repair work is usually divided into three classes: (1) Block pavement repairs; (2) cement-concrete pavement repairs; (3) bituminous pavement repairs; (4) macadam, gravel, and earth road repairs, and (5) bituminous surface treatments. These classifications involve different characters of work, each requiring special knowledge on the part of those engaged in the actual performance of the physical work. Stone block, wood block and brick repairs, for example, require skilled laborers who have made a specialty of this work and are employed under the title of pavers and rammers; while repairs to sheet-asphalt and other bituminous pavements must be performed by men specially trained in this line of work, in addition to the necessary force engaged at the mixing plants. Broken stone road repairs, the care of earth roads, and bituminous surface treatments, also require men specially skilled, and while it is desirable to train the gangs for each particular branch of work under this classification, these subdivisions can be handled by those directly in charge of this division by training the laborers for the particular work to which they are assigned. It readily will be seen that this force, in the first place, can only be employed when the weather conditions are favorable for the work which makes the organization much more difficult to control and keep up to a proper standard than one composed of men regularly employed all of the year. Moreover, the indefinite character of the work necessitates greater elasticity in the organization than does street cleaning, and makes it a still more perplexing organization to operate with success.

There is no definite schedule for a street repair maintenance organization to work on, and there are no fixed rules that can apply to all repair work other than that when repairs are required, they should be made at once. The materials to be used and the method and manner of making repairs are variable quantities for which only general principles can be set forth, which, of course, means that the organization coping with the work must be well trained. Work of an indefinite character opens up a channel for innumerable excuses and to be successfully coped with, requires a certain amount of initiative on the part of each and every man from the laborers to the chief engineer, which makes their good will a necessary adjunct. The men should be taught to understand the relationship between their particular function and the work as a whole. This can be brought about thru the installation of unit cost records, which, together with an educational campaign, consisting of meetings held every so often for the purpose of making clear the method of handling the work and each man's part in the

work, will bring about a friendly rivalry between the different repair gangs. These meetings mean a great deal, as they set the men thinking, open up a new vision to them, and put them on their mettle, which will ultimately result in improving their opportunities.

Emergency Maintenance. This includes snow removal, and it is unnecessary to dwell on the fact that no matter what appliances may be on hand for the removal of snow, the actual performance of the work is dependent upon the efficiency of a thoro and systematic planning of the operations, dividing and subdividing the territory into sections covering areas of such a size that the work can be thoroly and readily controlled by the supervising force. This work arises suddenly and must be performed in such a short space of time that it requires more supervision probably than any other branch of work, and it is for this reason it can be better and more quickly handled by so dividing that each and every one controlling the work will be responsible for a certain definite area. This principle is true of any city, independent of its size. The supervising force selected to control the work must be thoroly instructed, before the winter sets in, and imbued with a spirit of enthusiasm and pride in their part of the work. They must be available at all times, day and night, keep track of the weather conditions thru the main office where the latest weather reports should always be available, and, as soon as the indications point to a storm, each and very one in the organization must set to work to get his equipment out on the street at the earliest possible moment. This necessitates getting in touch with the contractor's teamsters, etc, and all the men assigned to a district in order that they may start out immediately the snow shows signs of making any headway which means, of course, as soon as it begins to cover the pavements. From that time on, the whole organization must work day and night fighting the storm.

8. Methods of Systematizing Work

Systematizing the work requires a very careful study of all the activities of the department from the ground up and their relation to one another, as the primary consideration should be to do away with as much unnecessary routine as is possible and still have an adequate system of control and one that embodies the compilation of all relevant data of value as a permanent record. Systematizing means simplifying the work, the bringing about of a maximum of efficiency with a minimum of energy. In a highway department, where the activities are so closely related that there is very apt to be an overlapping of jurisdiction and duplication of work, it is obvious that a thoro systematizing of the work is essential.

The tendency is to standardize and control work in a manner that will not only conserve energy and do away with unnecessary duplication, in so far as individual effort is concerned, but to concentrate our forces so that we can efficiently and economically carry on our operations along the line of least resistance, as ease of operation is one of the most important factors to be considered in any working organization, and, for example, in a municipal or town highway department, there is no step that would accomplish more in this direction than the combination of the highway construction, maintenance, street cleaning, and the collection and disposal of ashes, rubbish and garbage, under the jurisdiction of the one organization. This would also have the added advantage of placing the street cleaning work more generally on an engineering basis, which would undoubtedly lead to more sanitary methods of cleaning, and to methods that would be more apt

to take into consideration the maintenance and care of the pavements themselves than is likely to be the case where the street cleaning is not under engineering supervision.

Systematizing of the work and establishing a sort of *esprit de corps* are both essential adjuncts to an efficient and economic administration of a highway or any other department. Numerous highway departments have men who are loyal and enthusiastic, but their work is not conducted on an efficient and economical basis because it is not systematized. The best method of establishing a permanent spirit of coöperation is brought about thru arousing the interest of each and every employee, high or low, thru establishing a definite procedure to govern each function and operation. Under such a system, each employee assigned to any subdivision or operation coming under the jurisdiction of the department will immediately inquire what relation his task has to the work to which he is assigned. This will lead to his studying the forms, charts, etc, and will naturally arouse his interest, and therefore a thoro systematizing of the work and a definite procedure governing each and every operation is essential.

In order to illustrate this point, let us consider for example the effects on an organization of establishing a definite procedure for the work of the maintenance forces. Under the old system the foreman kept the time of the men and noted the material received for the work and after the job was completed, the unused material, if any. This account he turned in to the main office. He was responsible for the time the men put in on the work and the amount of work performed. No records, however, were kept permitting an analysis of the efficiency with which this work was performed so that the foreman had no means of knowing whether he was performing his work in an efficient and economical manner. Under the circumstances it is perfectly natural that his one object was to turn in the time of the men and to perform the work, not necessarily in the shortest time possible or at a reasonable cost. Now, as soon as a definite procedure is installed to control such work, the foreman is given job orders or route sheets noting the work he is to do and the order in which it is to be performed; the time sheets, thru which the time of the men is kept and charges against the specific parcels of work; material sheets, thru which the material is charged up in the same manner; all of these are designed to bring down the cost of the work to a unit square yard basis, both with reference to cost of material and labor. At first these forms and records are apt to confuse the old type of foreman, but after he has been thoroly instructed in their use and has been using them for a time, it will be found that he is more enthusiastic over the work than he has ever been, and has inculcated this spirit in the laborers in his gang, with the result that not only is the work done at a lower cost but it is done in a more efficient manner.

The general principles set forth in the outline of the several procedures, such as planning boards, correspondence, contracts, unit costs and permits and licenses, as described in Arts. 9 to 13 inc, can be utilized in any highway engineering organization by making the necessary modifications to suit the conditions under which the respective departments intend to or are operating.

9. Planning Boards and Visible Records

As a means of insuring a more thoro and intimate knowledge of the status of the operations coming under the jurisdiction of a large highway department than that afforded thru up-to-date records and definite procedures

for each operation, it is necessary to supplement these records and procedures with planning boards, containing a graphic representation of the status of the operations in such a manner that the work can be more readily controlled than is possible where it is necessary to constantly refer to office records. No matter how thoroly the operations of a highway department may be systematized, where the heads of the different units of the organization are dependent upon daily consultations and studies of the records on file to enable them to picture in their minds the status of the work under their jurisdiction, there is always a certain amount of lost motion and unbalancing of the work, resulting in one locality receiving undue consideration at the expense of another or delays in the starting of important contracts due to unconsciously yielding to outside influences interested in pushing forward less important work. This new scheme for controlling the work of a department thru visualizing the operations enables the executive and division heads to at any time obtain a picture of the status of the operations coming under their respective jurisdiction, and is the most-up-to-date system heretofore employed in highway departments or industrial corporations to simplify carrying on the work in an orderly and systematic manner. Planning boards have, after a thoro trial, proved an unqualified success and one of the most practical means that have been thus far developed for simplifying the management of such a department.

This method of visualizing the status of the work also enables the executive to readily give information concerning the operations under his jurisdiction that would ordinarily necessitate communicating with the offices where the records are kept, resulting in a delay of several minutes before the information could be obtained from the record files.

Philadelphia Bureau of Highways Planning Boards. The following principal objects were sought in connection with the installation of the system of planning boards in Philadelphia by the author while Chief of the Bureau of Highways and Street Cleaning, 1912 to 1917:

1. The establishment of a means of providing the chief engineer, the division engineers and the several district assistant engineers and their subordinates with a continuous and complete, concise and easily accessible graphic record of all authorized prospective construction and maintenance work, and of the current status of all work under contract or in course of prosecution under their respective supervision, in order that they would be enabled to plan and administer the work in a more systematic, economical and efficient manner.
2. To eliminate as far as possible the necessity for the engineers to make daily or perhaps constant reference to, and studies of, the regular filed office records in order to enable them to form a mental picture of the status of the work under their jurisdiction.
3. The institution of a practical means of controlling or equalizing the quantity of work to be performed in different localities, and in determining the sequence in which the work could be prosecuted to the best advantage, and to assist in the subsequent assignment or distribution of the engineering, inspection and working forces.
4. To facilitate the prompt determination of any general information relating to the construction and maintenance work that may be sought by the public and that otherwise would not be available except after more or less detailed investigation with a resulting consumption of time.

Equipment. The equipment which has been provided in connection with the planning board system includes the following:

1. Planning Boards, which have been installed in the offices of the chief engineer, the 2 division engineers and the 7 district assistant egnineers in charge of general highway work and the division engineer in charge of bridge and sewer maintenance.
2. Legends, which while standard in all possible details, necessarily vary more or less in order to adequately provide for the specific data indicated on the four general modifications of the planning board in use.

3. INDICATORS, pins and thumb tacks of various sizes, shapes and colors suitable to indicate the designations shown on the legends.

4. CURRENT STATUS VISIBLE RECORDS, two forms, one each respectively for contract work and for municipal force work, and one form for extensive special construction work for the information of the chief engineer; and one form in three parts for the use of district assistant engineers. Upon these several forms are indicated the pertinent details and the current status of all work authorized, under contract and in course of prosecution.

5. CURRENT STATUS RECORD FILES, which consist of a visible card filing device for the chief engineer's office and clip filing boards in the offices of the district assistant engineers.

6. DAILY PROGRESS REPORTS, which indicate daily both graphically and analytically the nature and quantity of work performed and other pertinent data for each job.

General Construction of the Planning Boards. In general, the planning boards consist of a map enclosed in a wood frame, of either the entire city or the portion included in the district or division under the respective engineer's jurisdiction. The scale of the map is made sufficiently large to permit the necessary details to be shown with ample facility. The maps on the planning boards in the offices of the chief engineer and the division engineers are drawn to a scale of 1000 ft to the inch, while those in the offices of the district assistant engineers vary between 200 ft to the inch in the congested central districts to 500 ft to the inch in the outlying districts. The enlargement of the scales of the several district planning board maps is due to the need for a greater space in which to record the more refined details which it is essential should be known and reckoned with by the district assistant engineers, but which need not, however, be considered in such detail by either the chief engineer or the division engineers. The maps contain, for the territory covered, a complete and accurate record of the highways physically opened and also of those not physically opened but on the city plan. On all physically opened highways, the characters of the existing roadway pavements are indicated by colors. Where a highway contains two or more varying types of pavements, that is, the gutter or track pavements differing from that of the shoulders, the actual existing pavement conditions are indicated on the district assistant engineers' maps by properly coloring the relative portions of the highway. The fact of a pavement being under maintenance guarantee is indicated by wide pencilled hatching superimposed on the character of pavement coloring and which is erased upon the expiration of the guarantee period. The existence of railway tracks is indicated by solid black lines upon which is placed a symbol indicating the name of the ownership. A single line indicates a complete track structure and the number of separate complete track structures existing on a highway is indicated by a corresponding number of single lines. The maps are securely mounted with paper-hangers' paste upon a wood fiber board $\frac{3}{8}$ in in thickness, which is securely nailed to the wooden backing of the frame enclosing the map. The planning board is fastened securely to the office wall and in such a position that it may, if possible, be adequately illuminated by daylight, and that shadows will not interfere with its operation. Where artificial illumination is required, this is supplied by means of a special trough mirror reflector containing a number of switch-controlled tubular tungsten electric incandescent lamps and concealed in the canopy at the top of the planning board frame.

Legends. In devising the legends (see Fig. 6) an effort was made to have them mnemonic, that is, to assign indicators of such shapes, sizes and color as would by their appearance readily associate themselves with or identify the work or condition they were intended to represent. All data or information of a fixed or semi-permanent nature is indicated by properly colored and specifically symbolled circular flat-headed thumb tacks which are inserted flush with the surface of the map. In order to facilitate reference to information in greater detail, these indicators also each contain an identifying serial number which refers to lists annexed to the planning board which indicate full information relative to definite locations, names of ownerships, etc. All data or information of a temporary or variable nature is indicated by means of colored glass-headed pins. Three sizes of pins, as relating to the size of the glass head are used, but all of the pins have short stems which permit the glass head being inserted close to the map surface. In instances where two or even three conditions need be indicated by a single pin, this is accomplished by using pins whose heads contain two or three properly colored concentric circles.

LEGEND

PERMANENT DESIGNATIONS

GENERAL:

- (Red) Main Highway Office
  NOTE: In the following indications, the numerical designations of districts are indicated by numerals.
- (Red) District Highway Office
- (White) Service District. Street Cleaning and Ash, Rubbish and Garbage Collection
  NOTE: In the following indications, the serial identification numerals refer to correspondingly numbered detailed notes on lists annexed herewith.
- (Blue) Store Yard
- (Yellow) Dump, Ash Rubbish or Street Dirt
- (Yellow) Garbage Disposal Plant
- (Yellow) Rubbish Disposal Plant
- (Yellow) Stable, Service Contractor's
- (Black) Contractor's Asphalt Plant
- (Black) Municipal Asphalt Plant

EXISTING PAVEMENTS:

- (Blue & Black) Asphalt Block
- (Gray) Bituminous Macadam
- (Green) Cement Concrete
- (Pink) Cobble or Rubble
- (Blue) Sheet Asphalt
- (Red & Black) Slag Block
- (Purple) Stone Block
- (Yellow) Unimproved, Graded, Dirt, Cinder, etc.
- (Red) Vitrified Block
- (Brown) Waterbound Macadam
- (Black Hatched) Wood Block

MISCELLANEOUS:

- (Black & White) Railroad Siding
- District Boundary Line

TEMPORARY OR VARIABLE DESIGNATIONS

CHARACTER OF AUTHORIZED CONSTRUCTION WORK:

- (Yellow) Grading

PAVEMENT:

- (Gray) Bituminous Macadam
- (Green) Cement Concrete
- (Blue) Sheet Asphalt
- (Purple) Stone Block
- (Red) Vitrified Block
- (Brown) Waterbound Macadam
- Wood Block

INDICATION OF LIMITS OF WORK:

- If Highway is not Colored
- If Highway is Colored
- If necessary in conjunction with the previous indications to show limits of contiguous authorizations.
- (Yellow) If Work is that of Surface Treatment

WORK DETAILS:

- (Red & Yellow) Urgent necessity for prompt performance of work
- (Black & Yellow) Materials Ordered
- (Black & Yellow) Materials Delivered
- (Black & White) Contractor's Asphalt Repairing Gang: General Working Location
- (Black & White) Municipal Asphalt Repairing Gang: General Working Location

MISCELLANEOUS:

- (Black) Ordinance pending to authorize Work
- (Yellow) Outstanding Tickler. Indicating the existence of open relative correspondence

DETAILED INFORMATION:

Full detailed information relative to the current status of the legal, contract, structural and other governing conditions pertaining to all work posted on this planning board is indicated on the individual card records for each specific authorization in the Current Status file.

TECHNICAL CLASSIFICATION AND STATUS OF WORK

CONTRACT WORK:

	Authorized	Contract executed or in course of execution	Work in progress by contractor	Authorized but cannot be placed under contract for cause	Under contract but work cannot be started for cause	Work started but is now suspended for cause
Grading	(Light Green)	(On White)	(On Red)	(On Black)	(On White & Black)	(On Red & Black)

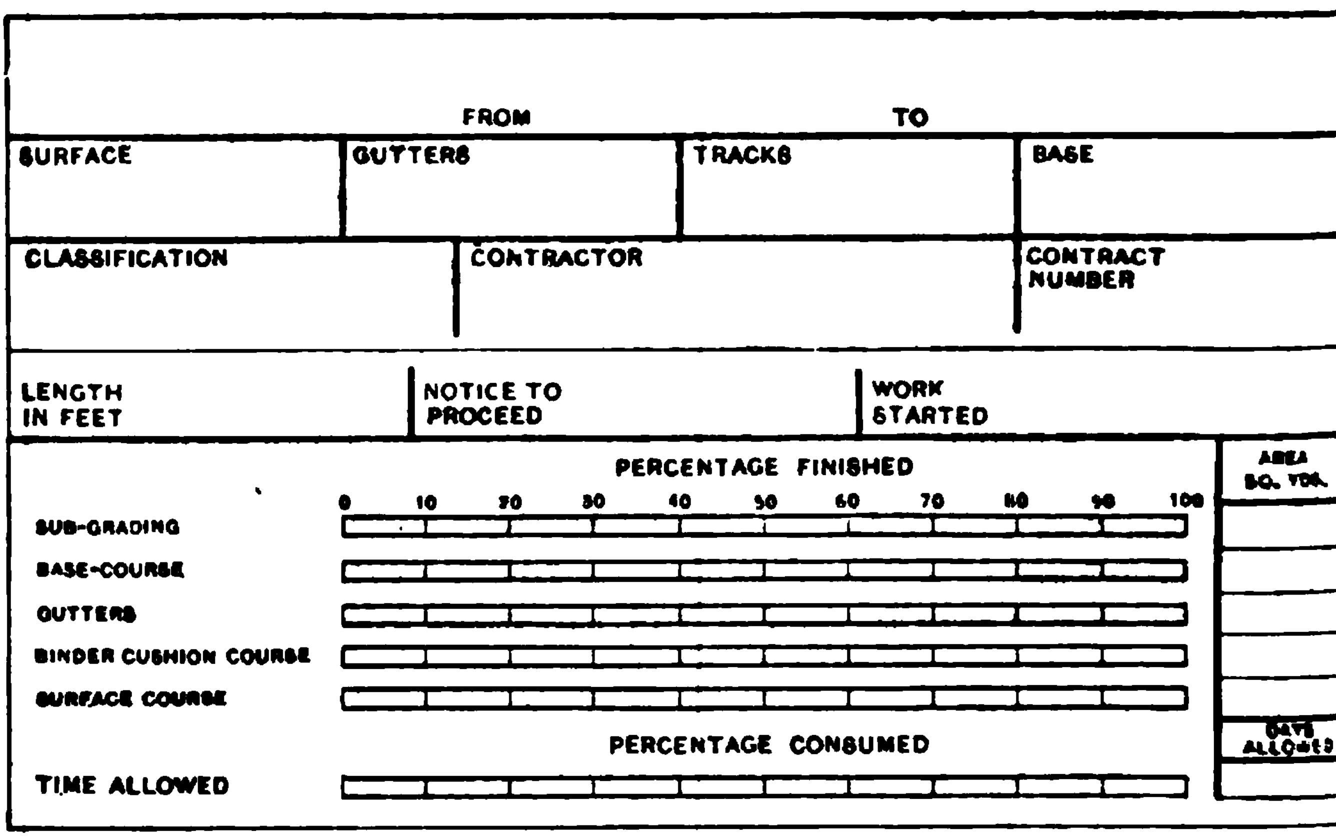
Repaving	(Blue)	"	"	"	"	"
Surfacing	(White)	"	"	"	"	"
Resurfacing	(Brown)	"	"	"	"	"
Special Construction Work	(Dark Green)	"	"	"	"	"

MUNICIPAL FORCE WORK:

	Scheduled	Work in progress by Municipal forces
Extensive Surfacing, Resurfacing and Repaving	(Gray)	(On Blue)
Dust Layer Treatment	(Crystal)	"
Bituminous Surface Treatment	(Yellow)	"

Fig. 6

Operation of the Planning Boards and Current Status Records. The responsibility for the prompt and accurate posting of the planning board and current status file is centralized in one person in each office, and this posting is done early each morning from the reports received of the operations, transactions, and changes in conditions occurring since the time of posting on the previous day. The posting is done by the insertion or removal of pins of the proper shape, size and color. In the district offices, however, the record of the need for the performance of any character of repair work is posted as soon as the necessity becomes apparent from any source, such as being reported by a patrol inspector; resulting from observation by the district assistant engineer or any of his subordinates; notice from the main highway office or any other municipal department, from the police or from the public. Where two or more different characters of pavement exist upon a highway, the indicator pin is placed upon that portion of the highway which indicates the character of pavement requiring the repairs which may be the track, the shoulder or a gutter. All instructions from the chief engineer or the division engineer to the district assistant engineers to investigate conditions or perform any work at a definite location are posted on the planning board



Form A

as an outstanding tickler which constitutes a current record of all such matters not closed out by a final report to the main office. The trouble marker is used to indicate any retarding condition relating to either an administrative detail or the physical work, such as legal obstacles preventing authorized work being placed under contract and delays, interruptions, or suspensions of work in progress, etc. Of course, all indicator pins are removed immediately after the indicated conditions are found no longer to exist. When the finished work is that of original pavement or such other work as results in a change in the character of an existing pavement, the map is posted by being properly recolored to indicate the new type of pavement surface.

Routing the Repair Work. In the several district highway offices and in the division of bridge and sewer maintenance, the daily route sheets indicating the work to be performed by each municipal repair gang are prepared by direct reference to the planning board, where every condition such as general repairs to a street or even an isolated defect in a pavement is specifically indicated and in the order of their importance. The routing of the repair gangs is one of the most important functions of the planning board. The pins indicating work in progress by the municipal forces also contain a serial number which identifies the name of the gang foreman in charge of the work.

Current Status Records. In addition to the data regularly carried on the planning boards there is also certain other data of a more detailed and extensive nature relative to the current status of the legal, contract, structural, and other governing conditions,

which should be readily accessible but which on account of their multiplicity it would not be practicable to indicate on the planning board. This information is recorded in a very accessible manner by means of individual card records properly filed in visible filing devices which are located adjacent to the planning boards. Three forms of current status card records are provided, one form being for municipal force work and one form for contract work, both of which are used in the chief engineer's offices. These records are so designed as to permit the indication in a concise manner and in logical sequence of all the pertinent information relative to current conditions. The design of the current status record form used in connection with the district planning boards is such as to make it possible to post graphically from the inspector's daily progress reports, either daily or weekly as may be desirable, the percentage of each portion of the work finished and the percentage consumed of the total time allowed for the completion of the work (see Form A).

Inspectors' Daily Reports. Each inspector having supervision of construction or maintenance work is required to submit daily reports in such detail that, in addition to their other purposes of record, they furnish the data necessary to the prompt current posting of both the planning boards and current status records. The daily progress report on each job as submitted to the division engineer by the inspector is printed on a postal card and the most recent one of the reports for each job is daily inserted on a visible filing board, thus constituting an economically operated current status record.

10. Unit Cost Records

Unit cost records serve as a basis for determining upon future appropriations. They also serve as a means of control over the operations of the department, bringing out the strong and weak points in the organization and the economy and efficiency with which the work is being performed, both by comparing the different units of the organization with one another, and the different characters of work of the department with different units of the organization and like work in other localities.

These costs, principally in repairs to pavements, bituminous surface treatments, street cleaning, and other classes of work that can better be done by day labor forces, employed directly by the highway departments, than by contract, will be a most important factor in enabling any department to make greater strides toward putting this work on an efficient and economical basis. Records of this kind are invaluable as a means of control in conducting work coming under the jurisdiction of any highway organization, and will result in bringing about a spirit of rivalry between the different subdivisions and units of the organization.

The moral effect on an organization is alone a justification for keeping unit cost records. This is illustrated thru the pride aroused in the men in connection with their work. The natural instinct of man is to excel in his undertakings, but we must remember that men will be led and not driven, and if we are to get the best out of them we must arouse their interest in their work and impress them with a sense of their responsibility and there is no better way to do this than thru the friendly competition resulting from the use of the unit cost records.

In some quarters there has been a rather general impression that the necessary job orders, route sheets, time sheets, material reports and progress reports which the foreman is required to handle, are apt to confuse him and consequently tend to decrease rather than increase the efficiency of his work. This is not so; on the contrary it tends to develop the foreman, awaken his interest, and in many instances makes a new man of him because he is placed on his mettle, taken in to a certain extent on the financial and business end, made a more important factor in the organization, and consequently his work means more to him than the mere physical results.

Value of Unit Costs. To insure the efficient administration of any commercial or engineering organization, certain well-defined fundamental laws of management must of necessity be recognized and adhered to. Among the foremost of these laws is the one emphasizing the importance of a determination of the unit costs of performance or production. An organization and its administrative equipment may presumably be ideal in every respect and yet in the final analysis not produce the results or accomplish the purpose for which it was created. It is a knowledge of the unit costs of the organization's performances that places the executive or managing officer in possession of the facts it is most necessary and essential he should know. As unit costs constitute an absolute and true index of the relations between funds expended and results accomplished, this subject in so far as it relates to public work activities is properly becoming more and more the concern of a critical public.

An illustration of the advantage of keeping records of this kind was in connection with the bituminous surface treatment work, which is the principal factor in modern highway maintenance of water-bound macadam streets and roads, in Philadelphia during 1913 and 1914. The unit cost records of this work formed in 1913 showed an average cost of 7.3 cents per sq yd, while in 1914, the average cost was 5.8 cents per sq yd, or a saving of 1.5 cents per sq yd over 1913. This saving was a direct result of making an analysis of the items of cost for 1913, thru which it was possible to point out the weak points in the performance of the work, with the result that in 1914 more attention was given to the different operations of the work, the cost of which was considered to be too high the previous year. Of this saving of 1.5 cents per sq yd, about 0.5 cent per sq yd was due to the fact that a number of the treatments were second applications and naturally required a lesser amount of bituminous material per square yard, and the reduction in the cost of gravel, but approximately 1 cent per sq yd, or a saving of 14% of the entire cost of the work, was entirely due to the increased efficiency of the organization in handling the work.

Information Obtained from Unit Cost System. Aside from furnishing data calculated to justify or discredit the existence of an organization, or the outlay of funds for the accomplishment of a definite function or purpose, unit cost reports assist in determining certain matters of policy and administration. The maximum possibilities of a unit cost system naturally vary with the conditions existing in the organization in which it is operated. In installing the unit cost system the following objects should be sought:

1. To ascertain the quantity, and total and unit cost of each class of work performed, which will provide data to facilitate the preparation of budget and prospective work estimates and also afford a basis from which may be determined the fairness of unit prices bid on contract work.

2. To provide data to assist in the determination of the time beyond which it would be undesirable for economic reasons to continue maintenance work on existing roads or pavements, or in other words, the time when replacements must be contemplated.

3. To secure by interpretation of the data, knowledge as to the efficiency of performance of a department's forces, and to assist in showing the adequacy of the service rendered to the public.

4. To show the quantity and cost of each class of work performed within the boundaries of any district, or unit length of highway, or on any specific structure or job.

5. To show separately the varying and principal elements of expense, such as labor, hauling and materials, entering into the cost of each class of work.

6. To produce in the subordinate employees the beneficial moral effect resulting from a realization that records of their performances are brought to the attention of their superiors.

7. To promote friendly competition between similar units of the organization and establish a sort of *esprit de corps* among the men.

As in most localities the construction of highways is under contract, all the work performed by the department forces is that of maintenance. It is possible to design a standard unit cost system sufficiently flexible to permit its application to any class of maintenance work. The principal general classifications into which the maintenance work performed by department forces is divided, and for each of which a complete distinctive unit cost system should be provided, are as follows: (1) Highways; (2) street cleaning; (3) bridges.

Unit Cost System for Maintenance of Highways. Except in minor details the procedure for each of these systems is similar. Considering this, and also the fact that while the procedure for the highway maintenance repair unit cost system includes greater variations from the standard, and at the same time also embodies all of the standard principles governing the systems for the remaining classifications, these will be omitted in favor of a description of the general conditions and considerations governing the highway maintenance repair unit cost system, in a large municipality, which, with the necessary modifications, can be used for a state, county or township highway department. This work should be subdivided into two general sub-classifications as follows:

1. Restoration work, which includes the replacement of highway pavements opened by individuals or public utilities, for which the municipality receives remuneration, and the replacement of pavements opened by any municipal department.

2. General maintenance work, which includes all work done on the highways and not included under (1).

To facilitate the reporting of field data, the work included in the two preceding general sub-classifications should be divided into the three following divisions:

1. Restoration and maintenance of streets.
2. Restoration and maintenance of roads.
3. Bituminous surface treatment and sprinkling.

Maintenance Chargeable to Different Funds. All of the work performed in a municipality, both restoration and maintenance should be chargeable to either of the two following funds. (1) City fund; (2) street railway assessment fund. This division of funds is occasioned by the fact that in some municipalities the street railway companies pay annually to the city a fixed amount to compensate the municipality for the maintenance and replacement of roadway pavements on the highways occupied by their tracks. The fact as to whether or not the highway on which the work is performed is occupied by the street railway company's tracks should be reported by the foreman in charge of the work and this should govern the fund against which the work is charged.

KINDS OF FORMS USED. To provide for the operation of the unit cost system and the attainment of the objects for which it is instituted, the following set of forms should be provided:

1. A schedule of mnemonic symbols representing each and every class of work likely to be encountered.

2. Daily route sheets, one each for restoration work and maintenance work respectively.

3. Material issue orders.

4. Composite labor, material, hauling and progress record forms, one each for pave-

ment restoration and maintenance; road restoration and maintenance; and, surface treatments and sprinkling, respectively.

5. Cost record forms.

6. Highway maintenance record forms, one each for blocks and intersections respectively. Note: For the purposes of the maintenance records a block is considered to be a length of highway lying between the near curb line of the two nearest main intersecting highways, and an intersection is considered to be that portion of the main intersecting highways lying outside of the curb lines.

7. Printed instructions, enclosed in a pocket folder, explaining in detail the use of the forms and the general operation of the system.

To insure universal and definite knowledge concerning the operation of the unit cost system, every employee having to do with the system should be provided with a schedule of work symbols (see Form B) and a set of written instructions (see Form C).

On all of the forms, two colors of ink should be used in column headings, red indicating that the data will be supplied by the office, and black indicating that it is to be supplied by the gang foreman. Wherever practicable the data supplied by the office should be typewritten. Gang foremen should not be permitted to make or keep any records concerning the work except on the indicated forms and these entries should be made while actually engaged on the work.

Field Use of Forms. Except when a longer period of time is required to finish a specific parcel of work, the gang foreman should be provided each day, by the district office, with a Route Sheet, Form D, indicating the location and order in which the work is to be performed that day, separate forms being used for restoration work and maintenance work respectively. For each class of work the gang foreman should enter the work symbol and the length, width and area of the work performed. Upon completion of the work, he should sign and transmit this report to the district office for approval by the district engineer, who should then forward it to the main office.

On the first day of each week each gang foreman should be furnished with enough copies of the Time, and Progress and Material Sheet for that week. These forms should contain the district number and date, and the name, position and rate of pay of each employee in the gang. During the progress of each day's work the following data should be recorded on these forms by the gang foreman: the work symbol, placed in the spaces headed Order No., the fund, the time of arrival and departure on the job of each workman and team, the location of the work indicated by block or intersection, the length, width and area or thickness of work performed, the quantity and character of materials received and used, and the number of hauling trips made. After being signed by the gang foreman this report should be transmitted to the district office for the approval of the district engineer, after which it should be forwarded to the main office.

When it is necessary to use materials from stock the gang foreman should originate a Material Issue Order prepared in triplicate, upon which is printed "Please issue the following stores to bearer" and in addition, each copy should contain the following data: the district number, the date, the serial number, the name of storekeeper, the work symbol, the quantity, unit and description of material and the day and hour that the material is wanted, which is the time the team or agent leaves the job for the storeyard. The duplicate copy of the material issue order should be retained by the gang foreman and the original and triplicate copies presented by the driver or agent to the storekeeper who should record the time the team arrives, the time of issue of material to driver and the time the team departed, and should retain the original and return the triplicate to the driver for transmittal to the gang foreman, who should record the time of the receipt of the material and time of the hauling vehicle's arrival at the job. After being signed by the gang foreman the material issue order should be transmitted to the district office to be approved by the district engineer, and then forwarded to the main office. Whenever possible, however, the material issue order should be approved by the district engineer prior to its being sent to the storekeeper. The original copy of the material issue order which is retained by the storekeeper should be used in the posting of the balance of stores records.

Office Use of Forms. Upon the receipt of the record forms at the main office the entries on the time, progress and material sheets and on the material issue orders should be extended and totaled by the cost clerk, and, after being forwarded to the paymaster for his record of the employees' time, and returned, the following data should be entered on the Cost Record cards (see Form E) one of which should be originated for

each highway intersection and block; the district number, the work symbol, the fund, the date, the location, character and quantity of work performed, the foreman's name and the costs of labor, material and hauling. At the termination of any desired period of time there can be readily compiled from these cost records, the unit costs of any class of work performed in any geographical division, or the unit costs of the performance of any unit of the organization. With respect to classes of work where it is desirable to maintain cost records in greater detail as in the case of bituminous surface treatment work, these cost data may be readily compiled from the data reported on the time, progress and material reports.

From data contained on the Route Sheets received at the main office there should be noted on the reverse side of the Highway Maintenance Record cards which contain a detailed sketch, drawn to a standard scale, of each block or intersection, a record of the character, area and a graphical sketch of all pavement restoration and maintenance work performed on a number of the typical streets of each class of pavement that have not outlived their economical life. This makes it a simple matter to determine how the repairs are wearing as a repair over a previous repair would be brought out in the plotting. Where it is decided that it would be more economical to repave instead of repair a pavement, the repairing done pending the appropriation of funds for repaving should not be plotted, as the plotting is intended to serve only as a guide until the pavement has outlived its economic life.

A separate card should be provided for each block and each intersection of highway pavement. These records contain on their face side a record of the character and unit costs of the base and surface courses of the original pavement, and the name and address of the contractor, the dates of completion and guarantee expiration and the length of guarantee. At the close of each year from the data shown on the Cost Record cards for each highway block and intersection there should be recorded on the corresponding Highway Maintenance Record, the following data: The year, the total area repaired, the total and unit costs of pavement replacements made necessary for both restoration and maintenance, the total area of restoration work only, and the unit replacement cost per year per square yard of pavement covered by the record. These maintenance records will eventually serve as a basis upon which the discontinuance of maintenance and the need of entire pavement replacements should be determined.

Form B. Schedule of Mnemonic Symbols for Work Performed by Municipal Forces

G R: Repairs to guard rails, fences and other safety devices.

X: Any miscellaneous work not described above which should be further described under miscellaneous work on the progress and material sheet.

Form C. General Instructions to Employees Relative to the Operation of the Unit Cost System for Work Performed by the Municipal Forces in the Philadelphia Bureau of Highways

INSTRUCTIONS TO THE DISTRICT ASSISTANT ENGINEERS. *General:* 1. To insure a uniform and definite knowledge concerning the operation of the unit cost system, each employee having to do with the system must be provided with a copy of such portions of these instructions as may be necessary to the proper performance of the portions of the work done by that individual employee.

2. In these instructions the term "foreman" means the person in the field directly responsible for the work performed by the gang.

3. On the forms where two colors of ink have been used in column headings, red indicates that the data must be supplied by the district office and black indicates that it may be supplied by the foreman.

4. Wherever practicable the data supplied by the district office should be typewritten.

5. Each foreman should send in his report forms daily and these should be promptly approved by you and transmitted at once to the main office.

Character of Work Symbols: 6. Provide each foreman with a schedule of mnemonic character of work symbols and instruct him in their use.

7. The proper character of work symbols must be given on all route sheets issued to foremen.

8. See that the proper symbol is entered in every instance on each of the several forms where it is necessary to identify the expenditure of any labor, hauling or material with the character of performance necessitating it.

9. In the case of restoration work, it is necessary also to properly identify the work performed with the reason that made it necessary, and therefore there must be indicated in addition to the character of work symbol, the permit serial number preceded by either of the symbols "W," "P," or "X," which indicate respectively that the opening was originally made by the Bureau of Water; a public utility or individual which has paid a flat rate charge; or, some agency other than the two previously enumerated.

Route Sheets: 10. Except when a longer period of time is required in which to finish a specific parcel of work, you must furnish to each foreman for each day, a route sheet, indicating the district number, the date and the location, character symbol and order in which the work for that day is to be performed.

11. Separate forms must be used for restoration work and maintenance work respectively.

Material Issue Orders: 12. See that each foreman is at all times provided with a book of material issue orders and that they are used in obtaining all materials from either the storekeeper or other foremen.

13. You should be thoroly familiar with the manner in which material is being ordered and handled.

14. Books returned by foremen containing triplicate copies of material issue orders are to be filed in the district office.

Time, Progress and Material Sheets: 15. See that on the first day of each week each foreman is furnished with enough copies of the time and progress and material sheets for that week, separate forms being used for each of the following general characters of work: (a) City street pavement restoration and maintenance; (b) country road pavement restoration and maintenance; (c) bituminous surface treatment and sprinkling.

16. On these forms the district office must indicate the district number, the date and the name, position and rate of pay of each employee in the gang.

17. On sprinkling work, the number of gallons of water used should be indicated by the district office, as determined by knowing the capacity of each sprinkler and the number of loads consumed.

19. For the purpose of the unit cost and maintenance records a block is arbitrarily considered to be a length of highway lying between the near curb lines of the two nearest main intersecting highways; and an intersection is considered to be that portion of the main intersecting highways lying outside of the curb lines.

INSTRUCTIONS TO FOREMEN. *General:* 20. If you do not understand these instructions, or how to fill out the forms, ask the person to whom you report to explain matters to you.

21. In filling out the forms, you should write as plainly as possible. If it is possible for you to do it, all work symbols should be shown in printed capital letters. Write everything out in full. This will prevent misunderstandings.

22. Keep the forms in a clean and neat condition. Do not fold them more than is absolutely necessary. Carry the forms in the folder provided for that purpose.

23. Everything you enter on forms must be written in your own handwriting and while you are on the work.

24. Where two words are printed together, such as "Inspector" and "Foreman"; "a.m." and "p.m.,' etc, the word not required should be crossed out.

25. Do not write anything in the columns whose headings are shown in red ink.

26. Send your report forms to the district office at the close of each day's work.

Kind of Work Symbols: 27. If the kind of work symbol is not shown on your route sheets, get the proper symbol for the work from the symbol list. If it is possible to do so before sending in your reports for the day, ask the person to whom you report if you have selected the correct symbol.

Route Sheets: 28. The work must be performed in the order in which it is shown on your daily route sheets, unless the person to whom you report orders you to do otherwise.

29. If it is necessary to do any work not shown on your route sheets, make a record of it on the route sheet.

30. Send route sheets to the district office at the close of work each day. If all of the work shown on the route sheet has not been finished, strike out the unfinished work locations and transfer them to a blank route sheet which should be returned to the office on the following day.

31. For each item of work done, you must give its length and width in feet; and its location in measurements from the curb lines.

32. When you do all of the work shown on the route sheet, sign it with your full name.

Material Issue Orders: 33. When you order materials from the yard or from another foreman, fill out a Material Issue Order in triplicate, and give the district number, the name and location of the storekeeper, or foreman to whom the order is sent, the character of work symbol, the quantity, unit and description of the material ordered and the date and hour that the material was ordered. The duplicate copy of the material issue order must remain in the order book, and the original and triplicate copies must be given to the storekeeper, or foreman, who must write the date and time that the material was issued. The storekeeper, or foreman, must keep the original copy and return the triplicate copy to the driver to whom he issues the material. The driver must turn this copy over to you when he delivers the material and you must write on it the time that the material is received. If you make a mistake in making out a material issue order, all three copies must be marked "void" and the original and triplicate copies sent to the district office. When you have used all of the material issue orders in a book, the book containing duplicate copies of the orders must be returned to the district office. Describe all materials fully; that is, the sizes of crushed stone, pipe, etc, should be mentioned.

Time, Progress and Material Sheets: 34. During each day's work, enter the following information on the form for that date: The kind of work symbols; the kind of street

(city or P. R. T. Co.); the time of the arrival and departure on the job of each workman and team; the location of the work done, shown by the names of the highway, block or intersection or structure; the time spent on each kind of work for each man and team; the length, width and quantity of work peformed; the quantity and character of materials received and used; and the number of hauling trips made. Sign this form and send it to the district office at the close of each day's work. Be certain to write the information for each kind of work in the proper spaces. To help you in this, the several spaces to be filled out for each kind of work are marked with the letters "A" to "H."

Asphalt and Block Pavement Work: 35. Under "granite block," "vitrified block," "asphalt" and "concrete base," enter any work where these materials are used. If

Form E

the sizes of the blocks are unusual, this fact must be stated. If the concrete base is of any mixture other than 1:3:6, a note to this effect must also be made.

Road Work: **36. The words "macadam roads" mean all roads surfaced with crushed stone, whether having a telford or a macadam base; or having a bituminous surface treated or a water-bound surface.**

37. The words "earth roads" mean all other roads, except those surfaced with ashes or cinders, which roads must be included under the heading "cinder roads." If the material is not cinders, then state what kind of material it is.

38. All gutter work, whether new paving or repairing, must be entered under the heading "paved gutters." The cleaning and improvement of gutters on earth roads must be considered as a part of the general maintenance work on that class of road.

39. In the blank space under "cinder roads" must be entered the kind of work done.

40. Characters of work not provided for with printed headings must be entered under the "miscellaneous work" heading.

Sprinkling: **41. When sprinkling is done, the complete routes followed must be entered on a sheet attached to the time, progress and material sheet, and on this sheet each route should be preceded by one of the letters "A" to "H" to properly identify the entries with those on the time, progress and material sheet.**

42. The number of loads of water used on each route must be given.

Measurements: **43. Measure the length of all pavement repairs parallel with the highway on which the repairs are made; and, in the case of highway intersections the length of the repaired area must be considered as being parallel with the highway first mentioned in naming the intersection.**

44. Where it is convenient to measure the distances of repairs from the curb lines of any small intersecting highway, it should be done, and a note should be made on the back of the route sheet. Otherwise measurements must be made from curb lines of main intersecting highways.

The Maryland State Roads Commission's (39) uniform system of compiling the records of all expenditures is shown by the chart of Table I, the explanatory notes which follow, and Table II, which illustrates the method of distribution of expenses to Dec. 31, 1911.

Table I.—Chart Showing Distribution of Expenditures, Maryland State Roads Commission

Cost	Administration and legal	Commission's salaries and expenses.
		Commission's office force, salaries.
		Commission's office expenses.
		Commission's counsel, salaries, fees and expenses.
	Engineering, general	Chief Engineer's salary and expenses.
		Chief Engineer's office employees' salaries.
		Chief Engineer's office expenses.
		Chief Engineer's instruments and repairs.
		Chief Engineer's laboratory investigations.
	Preliminary	Engineers in charge, salary and expenses.
		Survey parties, salary and expenses.
		Office employees', draftsmen, etc, salaries.
		Office expenses, stakes, etc.
	Construction, reconstruction, maintenance	Engineers in charge, salaries and expenses.
		Office employees, salaries.
		Office expenses.
		Inspectors, salaries and expenses.
		Superintendents, salaries and expenses.
		Foremen, labor, teams, etc, pay of advertising.
		Materials consumed, expense for.
		Use of equipment, rental for and repairs.
		Rights-of-way and damages.
		Advertising.
		Miscellaneous.
	Equipment	Expense for.
		Transportation of and establishment.
		Renewals and depreciation.
		Salaries of men in charge of, etc.

Administration and Legal. COMMISSION SALARIES AND EXPENSES. Salaries paid to members of the Commission. Also all expenses of members of the Commission when engaged on the work of the Commission, such as railway fares, team and automobile hire, subsistence and incidental expenses.

COMMISSION, SECRETARY'S AND OFFICE EMPLOYEES' SALARIES. All the salaries of the Secretary of the Commission and of all bookkeepers, clerks, stenographers and office boys in the employ of the Commission in its main office.

COMMISSION, OFFICE EXPENSES. All office expenses of the Commission such as rents, telegrams, telephones, postage, messengers, books, typewriters, adding machines, stationery and office supplies.

COUNSEL'S SALARY, FEES AND EXPENSES. Salary of the Counsel and such fees as are necessary to be paid other attorneys in the legal proceedings of the Commission which, from their nature, cannot be charged direct to a particular road or county. Also the traveling, subsistence and other incidental expenses of counsel when engaged on the business of the Commission.

Engineering, General. ENGINEER'S SALARY AND EXPENSES. Salary of the Chief Engineer and his traveling, subsistence and incidental expenses when engaged on the business of the Commission.

OFFICE EMPLOYEES, EXPENSES. Salaries of the Chief Engineer's Secretary, clerks, stenographers and office boys.

OFFICE EXPENSES. Office expenses of the Chief Engineer, such as rent, telegrams, telephones, postage, messengers, books, typewriters, adding machines, stakes, instruments, stationery and office supplies.

SHOP LABOR AND MATERIAL. Labor and material used in the shop operated under the direction of the Chief Engineer.

TESTS AND INVESTIGATIONS. Cost of the time of chemists, physicists, or others engaged under the direction of the Chief Engineer in conducting tests and investigations together with the cost of the materials used in connection therewith.

Preliminary and Construction. ENGINEER'S SALARIES AND EXPENSES. Salaries and traveling and incidental expenses of all engineers engaged exclusively on Preliminary or Construction work. At present they consist of those of the Construction Engineer, the First and Third Assistant Engineers, and the Chief Draftsman.

ENGINEER INSPECTORS' SALARIES AND EXPENSES. Salaries, subsistence and incidental expenses of all Engineer Inspectors engaged exclusively on Preliminary and Constructive work.

OFFICE EMPLOYEES' SALARIES. Salaries of clerks, stenographers, office boys, etc, employed in the offices of the Construction Engineer, the First Assistant Engineer, and the Third Assistant Engineer.

OFFICE EXPENSES. Office expenses of the Construction and First Assistant Engineers, consisting of telegrams, telephones, books, typewriters, stationery, and office supplies.

Maintenance and Reconstruction. ENGINEERS' SALARIES AND EXPENSES. Salaries and traveling and incidental expenses of Engineers engaged exclusively on this class of work. At present they would consist of those of the Second Assistant Engineer, and vacations of inspectors.

ENGINEER INSPECTORS' SALARIES AND EXPENSES. Salaries and traveling and incidental expenses of all Engineer Inspectors engaged exclusively on Reconstruction and Maintenance work.

OFFICE EMPLOYEES' SALARIES. To this account should be charged the salaries of clerks, stenographers, office boys, etc, employed in the office of the Second Assistant Engineer.

OFFICE EXPENSES. To this account should be charged the office expenses of the Second Assistant Engineer, consisting of telegrams, telephones, books, typewriters, stationery and office supplies.

Preliminary. SURVEY PARTIES. To this account should be charged the salaries and expenses of engineers and their parties in the field, engaged in surveying and locating proposed new roads.

DRAFTSMEN. To this account should be charged the salaries of draftsmen engaged in preparing the plans and drawings for the proposed new roads.

Construction. All construction work should be done under regular contract or force work orders, which should bear distinctive numbers. An account should be opened

	Equipment, $47 480.88, 1%	Construction	Rental charge for average time at 5% per month equals		14 568.00
		Maintenance	Rental charge for average time at 5% per month equals		596.00
		Reconstruction	Rental charge for average time at 5% per month equals		800.00

for each such price of work, such accounts to be grouped as to funds from which paid and counties in which work is located.

RIGHTS-OF-WAY AND DAMAGES. Cost of land, acquired for right-of-way, expenses of appraisals, and of commissioners or arbitrators in condemnation proceedings, commissions paid for purchases of additional rights-of-way, payments for damages or repairs to abutting property and counsel's fees and expenses when specifically applicable to the cost of acquiring certain right-of-way.

GRADING. Cost of grading, including the cost of operating steam shovels, scrapers and grading outfits, the hire of teams and equipment, a rental for the Commission's equipment used and the cost of miscellaneous tools and supplies used on the work. The cost of grading done under contract should be charged this account from the vouchers in favor of the contractors.

SURFACING. Cost of all labor employed and material used in surfacing, including the cost of operating stone crushers, spreaders, road rollers, sprinklers and oilers, the hire of teams and equipment, a rental for the Commission's equipment used and the cost of miscellaneous tools and supplies used on the work. The cost of surfacing done under contract should be charged this account from the vouchers in favor of the contractors.

BRIDGES AND CULVERTS. Cost of labor employed and material used in construction of bridges and culverts, including the hire of teams and equipment, and the cost of miscellaneous tools and supplies used on the work. The cost of bridging and culverting done under contract should be charged this account from the vouchers in favor of the contractors.

DRAINS. Cost of labor employed and material used in construction of under or V-drains, including the hire of teams and equipment and the cost of tools and supplies used on the work. The cost of drain work done under contract should be charged this account from the vouchers in favor of the contractors.

ADVERTISING. Cost of advertising the terms under which contracts for the work may be let.

INSPECTION. Salaries and expenses of inspectors on the work.

SUPERINTENDENCE. Salaries and expenses of superintendents in charge of work done by the Commission's forces.

FINAL SURVEYS AND ESTIMATES AND PLANS.

Reconstruction. LABOR AND MATERIALS. Cost of labor employed and materials used in reconstruction of roads and turnpikes acquired.

TEAM HIRE AND USE OF EQUIPMENTS. Payments for hire of teams and equipment and a rental for the use of the Commission's equipment on the work. It should include the labor employed and materials used in operating and maintaining the equipment in use.

SUPERINTENDENCE. Salaries and expenses of superintendents and foremen in charge of reconstruction work.

INSPECTION. Salary and expenses of inspectors engaged on work of reconstruction.

Maintenance. LABOR. Cost of labor employed in maintaining existing roads.

MATERIALS. Cost of materials used in the maintenance of existing roads.

TEAM HIRE AND USE FOR EQUIPMENT. Payments for use of teams and equipment in the maintenance of existing roads together with a rental for the use of the Commission's equipment so used.

SUPERINTENDENCE. Salaries and expenses of superintendents and foremen engaged on maintenance work.

INSPECTION.

Equipment. Purchase price of all equipment which may have substantial value after it has been used on any particular piece of work, such as road rollers, crushers, scrapers, graders, sprinklers, horses and wagons, auto trucks, etc. Small tools and other equipment which quickly wear out or become valueless should be charged to the work for which purchased at the time of purchase and upon the completion of such work should be appraised and credited to it. The Commission's equipment should be inventoried and numbered and a proper record kept thereof. Charges for the use of the equipment should be made against the work on which it is employed the credits for which may be carried in a "Depreciation Reserve" account.

Rules for Distribution of General Accounts. The monthly total of the engineering expenses, specifically applicable to Preliminary and Construction work, should be

charged to Construction Preliminary and to Construction in proportion to the total amounts charged direct to those accounts during the month. The monthly total of the engineering expenses specifically applicable to Reconstruction and Maintenance, should be charged to Reconstruction and Maintenance in proportion to the total amounts charged to those accounts during the month. The monthly total of Administration and Legal and of the General Engineering expenses should be charged to Construction-Preliminary, Construction, Reconstruction and Maintenance in proportion to the total amounts charged direct, including the specifically apportioned charges for engineering expenses, to those accounts during the month. Exception: No part of the overhead charges is to be added to the maintenance expenditures made from the allotments of the Motor Vehicle Tax to Counties for maintenance of State Aid roads.

Rules for Segregation of Items of Work Done. GRADING. Under the head of Grading should be included all excavation, including ditch, masonry, culvert and bridge excavations, as well as the excavation covered by the cross-sections and from the borrow pits.

CULVERTS AND BRIDGES. Under the head of Culverts and Bridges should be included all pipes, boxes, as well as culverts and bridges of all kinds used toward the end of disposing the storm water coming to the road from above or from the surface of the adjacent lands.

UNDERDRAINS. Under the head of Underdrains should be included V-drains, blind drains, sumps, as well as the standard underdrains, and such other devices as are installed for the purpose of taking care of the ground, or sub-surface, water.

SURFACING. Under the head of Surfacing should be included, as well as the macadam or actual surfacing prescribed in the specifications under such head, all paved gutters, curbing, concrete or other breakers across the shoulders, gravel, etc, used for the shoulders, when so used particularly and independently of the grading expressly for the purpose of improving the shoulders, and any material such as sand, cinders or stone dust used as a layer between the subgrade and the surfacing proper.

MISCELLANEOUS. Under the head of Miscellaneous will be included only those items which cannot be reasonably placed in one of the foregoing classifications, and under the head of Remarks should be placed an explanation of any miscellaneous item amounting to over $100. Advertising may be placed in the miscellaneous column. Removing and rebuilding fences should be charged to right-of-way when possible. Guard rail for culverts should be charged to culverts and bridges. Guard rail to protect embankments should be charged to grading. Rip rap may be placed in the miscellaneous classification, but if amounting to more than $50, statement should be so made under the head of remarks. Catch basins and inlets, as well as storm water sewers along the road should go under the head of culverts and bridges. Pipes or ditches across private property as outlets to our culverts should be charged to right-of-way whenever practicable.

PRELIMINARY. This covers the work of the Engineering Department in making surveys, plans, calculations, investigations, estimates, specifications, etc, up to the advertising of the work for bids.

CONSTRUCTION. This is the work of the Commission or of its forces in the improvement according to the Preliminary plans, specifications, etc, of a structure, or the building of a structure *de novo*, on a section of a State Road in the State, or State-Aid Road, System.

RECONSTRUCTION. This covers the rehabilitation, serious repair, rebuilding or replacement of old structures on the turnpikes, or State-Aid Roads, taken over by this Commission for maintenance by it.

MAINTENANCE. This covers the work of preventing the deterioration of repaving, up-keeping, of treating with oil, pitch, etc, and generally of keeping in satisfactory condition the roads, and structures on them, under the charge of the Commission.

11. Correspondence Procedure

Purpose. In systematizing the work of a highway department it is very necessary among other matters of a fundamental nature that the correspondence procedure should receive careful consideration. In selecting

a proper procedure the following outlined system in operation in 1917 in the Bureau of Highways and Street Cleaning of Philadelphia is recommended as embodying all of the desirable features existing in the standard systems used by some of the best equipped business organizations and which would be applicable to the situation as presented in a highway department.

The purposes for which this procedure is intended to provide are as follows:

1. The centralization of the responsibility and of the operations of each detail of the correspondence procedure, involving the establishment of a central correspondence receiving, recording, routing and filing division; a central dictation room; and a central transcribing room.

2. The elimination or the reduction to a minimum of the possibility of loss or delay in the handling of correspondence, or of the destruction of the files by fire.

3. The installation of a logical and easily accessible subject classification filing system and of modern filing equipment.

4. The reduction to a minimum of the clerical labor expended in the operation of the correspondence procedure.

General Organization. The operation of the correspondence procedure should be under the general supervision of the chief clerk, to whom should report the chief stenographer and the stenographic force, mail clerks, complaint clerks, file clerks and messengers.

The STENOGRAPHIC FORCE should be segregated in one room to be used exclusively for transcribing. Adjacent to this room should be located the central dictation room, and the correspondence, receiving, recording, routing and filing rooms, and in order to insure privacy and to eliminate interruptions and the consequent loss of time, which is ever present when dictation is given amid the general activities of an office, all of the employees having dictation to give should be required to use the central dictation room. To further facilitate the systematic handling of this work, each correspondent should be assigned a stenographer and a definite period of time in which to dictate. These assignments should constitute a permanent daily schedule and no business other than dictation should be transacted in the dictation room.

The MAIL CLERKS should receive, register, route and dispatch all incoming communications other than service complaints which should be attended to by the complaint clerks. The file clerk should classify and file all correspondence sent to file and fill all requisitions for correspondence to be removed from the files. The messenger should collect copy and mail or distribute all local and outgoing correspondence.

INSTRUCTIONS, FORMS AND EQUIPMENT, as follows, should be provided to insure the systematic operation of the correspondence procedure: (1) Written correspondence procedure instructions; (2) acknowledgment postal card; (3) service complaint forms; (4) service complaint register sheet; (5) a routing direction form stamp; (6) mail register sheet; (7) reference register sheet; (8) schedule of mnemonic filing classification symbols; (9) metal filing and transfer cabinets, durable paper folders and metal-tipped index guides; (10) correspondence requisition; (11) carbon copy sheets, one each of distinctive colors for copies of registered correspondence, correspondence originating in the main office, and tickler copies; (12) tickler filing cabinets; (13) printed form letters; (14) reference report form.

General Operation. See Fig. 7. All employees having to do with the correspondence procedure should be uniformly guided by a set of writ-

ten instructions, which should cover in detail the routine procedure. Incoming communications may be divided into two general classifications as follows: (1) General correspondence or communications other than service complaints; (2) service complaints.

Receiving and Routing General Correspondence. All communications received at the main office, whether they be written, telephonic or verbal, should be transmitted in tangible form to the mail clerk. In the case of any communications where a definite or conclusive answer must be delayed until an investigation has been made, the mail clerk or complaint clerk should immediately forward to the author a postal card acknowledging receipt of the communication and advising that the department will give the matter prompt attention. On each individual incoming communication the mail clerk should stamp the routing direction form and on this direction form should be indicated the assigned serial registration number and the date of the communication's receipt. In order to afford a means of identification should it subsequently become separated, any relative data attached to or accompanying the original or first sheet of a communication should be numbered with the same serial number as is assigned to the first sheet of the communication. The routing direction form indicates in proper sequence the person or persons or the division or office that the communication should be referred to and what disposition is to be made of it. The names of persons regularly receiving routed communications should be indicated simply by agreed symbols consisting of the first one or two letters of their surnames or official designations. The disposition directions also indicate whether the contents of the communication are merely to be noted by the recipient or that a written or verbal report is desired, or that a reply to the author should be sent direct, or prepared for the approval and signature of a higher authority.

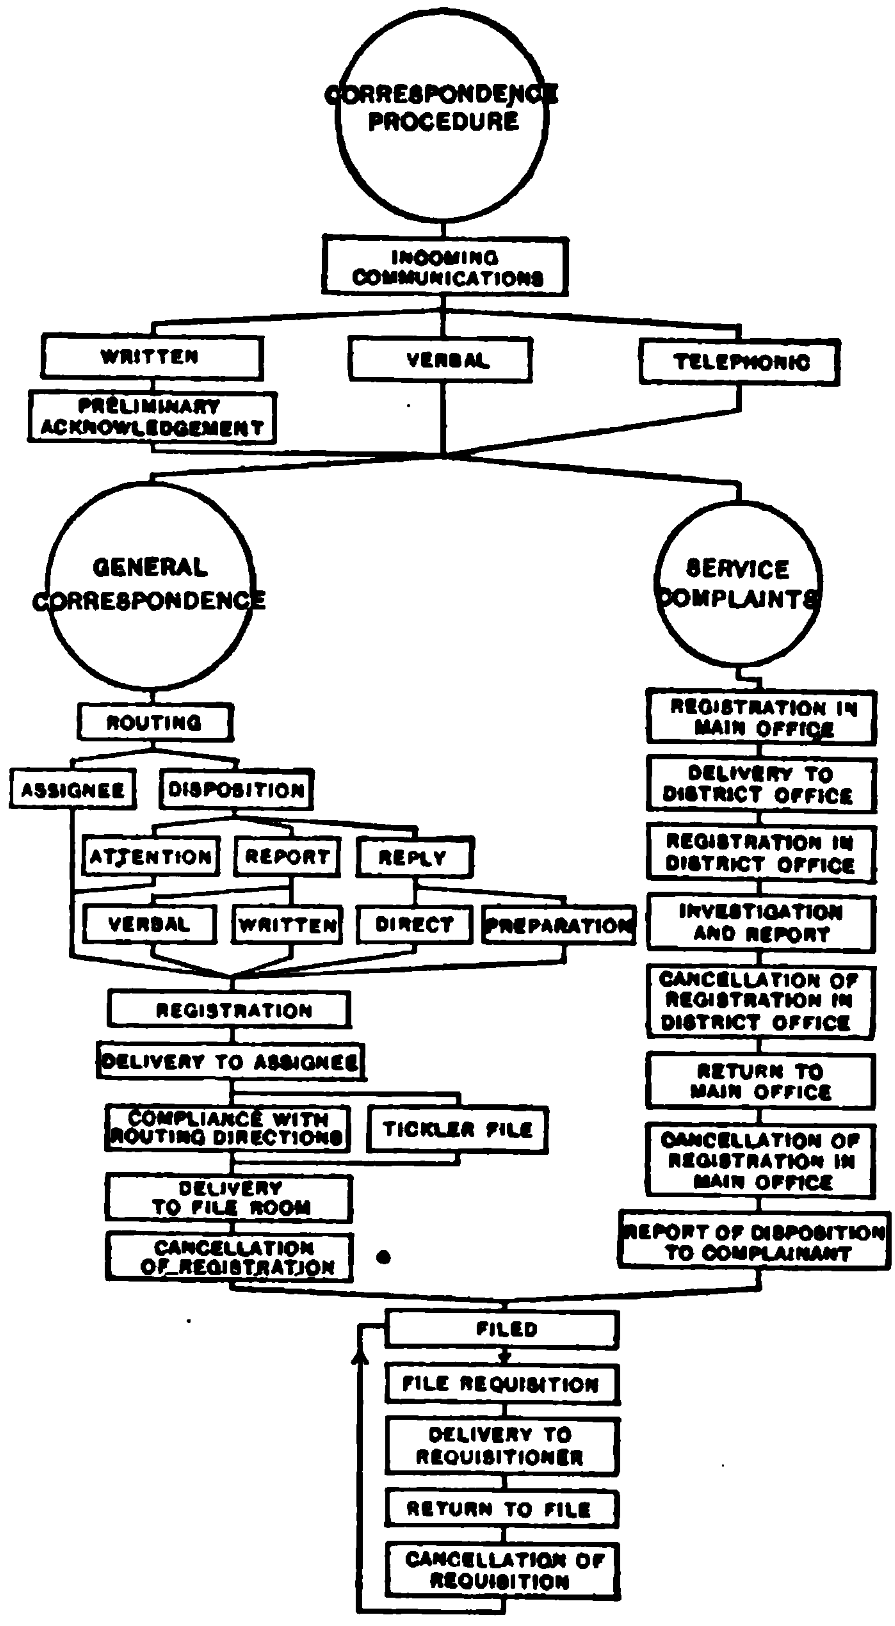

Fig. 7. Correspondence Procedure Administration Chart

After being properly routed the communications should then be arranged in numerical order and recorded upon the mail register sheet, the following data being indicated for each specific communication: The date of receipt; the registration serial number; the name of the author and the subject of the communication; and, the routing directions. This recording should be done in typewriting, the date being dictated

directly by the mail clerk to the typist. The mail register sheets are then filed chronologically in a loose-leaf binder and the communications distributed by a messenger in accordance with the routing directions.

Upon receipt of a registered communication the recipient should indicate in the routing direction form the date of its receipt and later on the date that the communication is subsequently forwarded to either another person or unit of organization or is sent to file. If it is necessary for the original recipient to refer the communication to another person or unit of the organization, the name symbol and the desired disposition should be indicated in ink on the routing direction form. All routing subsequent to the original routing by the mail clerk should be noted in the mail register by the mail clerk thru whose hands must also pass all referred communications. Once each week the mail register sheets for dates exceeding 1 week previous should be checked, and if necessary an investigation made of all entries not closed out by the return to file of the registered communications. If, during this investigation, it is possible to ascertain an anticipated return date, this date should be recorded temporarily in pencil in the mail register. On the 1st and 16th day of each month the mail register sheets upon which all entries are closed out should be removed from the active binder and filed in the inactive binder.

The registering and routing of communications make it possible to locate at any time any specific communication desired, and also place upon a person especially trained in the requirements of the work the responsibility for the intelligent routing and prompt distribution of communications.

Communications routed to the district highway offices should be, immediately upon their receipt, recorded alphabetically according to subject or name of author in the district reference register. In this register there should be indicated for each communication the following data: The serial reference or registration number; the name of the author; the subject of the communication; the date of receipt at the district office; the name of the person to whom referred, and date of such reference. The district reference register sheets should be filed alphabetically in loose-leaf binders and should be checked at frequent intervals, to insure prompt attention and the return to the main office, when necessary, of all correspondence.

Reports and Answering of General Correspondence. Reports on communications forwarded to the district highway offices for investigation should be prepared on report sheets in the handwriting of the person who made the investigation, and for this purpose copying ink or pencil should be used. These reports should contain the serial registration number of the original communication; the date of the investigation and the investigator's report and signature. After being approved by the district assistant engineer, these reports should, if so desired, be copied in a copying book and then forwarded to the main office, accompanied by and attached to the original communication. The entry in the district reference register should be closed out by noting the date of the return of the communication to the main office and the page number of the impression in the copying book.

Wherever practicable PRINTED FORM LETTERS, such as Form F given herewith, should be provided for routine correspondence originating in both the main and district offices, and also for certain inter-department correspondence where the uniform nature of the subject matter and the number of such similar letters make this desirable in the interests of economy and the saving of clerical labor. These letters should be printed in copying ink and should include all of the fixed data and provide blank spaces for the insertion of the variable data. When the routine practice requires the same subject data to be communicated to two or more different agencies the saving of time may be further facilitated by preparing the letters in duplicate, triplicate, etc, in one operation by the use of the carbon paper. The fixed printed form of both the original and duplicate copies of the letter should indicate the agency to which the respective copies are directed, and this should be further emphasized by printing the original copy on white paper and the duplicated copies on tinted papers. Practically all of the routine interdepartment and bureau correspondence may be conducted by means of printed form letters. When the number of letter forms used would not warrant the expense of printing, it is sometimes of advantage to prepare forms on some sort of duplicating machine, such as a mimeograph or hectograph.

DEPARTMENT OF PUBLIC WORKS
BUREAU OF
HIGHWAYS AND STREET CLEANING
ROOM 232, CITY HALL
PHILADELPHIA

WILLIAM H. CONNELL
Chief of Bureau

191....

Subject:—Request for preparation of Paving Contract No......
City Solicitor,
Philadelphia.
Dear Sir:—

Bids were received............191... for paving..........................St. from..............................Street, to.......................Street, with..., authorized by Ordinance of..............; and being low bidder, was awarded the contract.

The total cost of this work will not exceed $..................., and of this amount the cost to the City for paving intersections and in front of unassessable property will not exceed $..........................., to be charged against Item.......... This work must be completed within ....days after date of notice to proceed. The amount of penal bond required at...... percent of contract will be $....................., to be furnished by.............................

Please prepare contract in accordance with existing ordinances and accompanying proposal and specifications.

Yours truly,

APPROVED: Chief of Bureau of Highways.
Ass't Director, Dept. of Public Works.

Form F

CARBON COPIES should be prepared for filing purposes of all correspondence originating in the department, except that correspondence covered by printed form letters. Three colors of paper should be used for this purpose. Letters relative to communications having a serial registration number indicating their origin outside of the main office should be duplicated on orange tinted paper, while duplicates of all letters originating in the main office and therefore having no serial registration number should be prepared on yellow paper. When it is necessary or desirable that a tickler or follow-up be provided, an extra copy should be prepared on pink paper. The serial registration number shall be indicated on all carbon copies of registered correspondence and correspondents should be requested on the original of such letters to refer to this number in answering.

If so desired, in addition to the preparation of carbon copies for filing purposes all outgoing correspondence may be copied in LETTER BOOKS, separate books being used respectively for the various classes of correspondence, such as letters for subordinates in the main highways office; the district highway or division offices; inter-department correspondence; public utilities; contractors; and, miscellaneous which should include all letters not included in the several foregoing classifications.

Filing. For the purposes of public service work the SUBJECT CLASSIFICATION METHOD of correspondence filing is the one most generally used and it is especially adapted for a highway department where the activities, while varied, are also well defined. To facilitate the subject classification of correspondence a schedule of classifications and corresponding mnemonic symbols should be provided. This schedule should also indicate the manner in which the correspondence in each classification is to be filed, whether numerically by registration serial number, or alphabetically by author's name, geographical location, etc. The filing compartments should be arranged in the same sequence as indicated in the schedule of mnemonic symbols. When correspondence is ready for filing this fact should be indicated on the routing direction form and the correspondence should be collected and delivered by the messenger to the file clerk, who determines and indicates thereon the proper filing classification symbol, which symbol should also be recorded in the mail register opposite to the original record of the communication, together with the date upon which the communication is filed.

REMOVAL OF CORRESPONDENCE BY REQUISITIONS. No correspondence should be removed from the files except by the file clerk and then only upon requisition. These requisitions which are prepared in duplicate by the person desiring the issuance of correspondence, should contain the following data: The date of issue; the nature of the desired correspondence; the date of its anticipated return to file; the filing classification symbol; and, the requisitioner's signature. These requisitions should be given to the file clerk in return for the issued correspondence. The original copy of the requisition should be inserted in the folder in the place vacated by the issued correspondence, and the duplicate copy should be retained by the file clerk as a tickler to insure the return to file of the issued correspondence at the time indicated. Upon the return to the file of the issued correspondence, both the original and duplicate copies of the requisition should be surrendered to and destroyed by the individual to whom the correspondence was originally issued.

EQUIPMENT. Vertical steel filing and transfer cabinets, durable paper folders and metal-tipped index guides should be provided; their use ensures the convenient filing of correspondence in a safe and readily accessible manner.

Service Complaints. Service complaints include all communications relative to cases of alleged neglect, or of the unsatisfactory performance of such municipal services as street cleaning or the collection and disposal of ashes, rubbish or garbage. All service complaints received verbally or by telephone should be recorded directly upon a service complaint form. For the purpose of convenient identification, a distinct color of paper should be provided for complaints relating respectively to street cleaning, garbage collection and the collection and disposal of ashes and rubbish. On each of the forms there should be recorded the following data: The serial number and date of the complaint; the location and nature of the conditions complained of; the name and address of the complainant; and the name of the assumed responsible agency. When the complaint is embodied in a written communication it should be attached to the service complaint form and in these cases it is necessary to indicate on the complaint form only sufficient data to properly identify the complaint and to guide the inspector conducting the investigation. All complaints should then be recorded in the service complaint register preferably by a complaint clerk, the following data being indicated for each individual complaint. The serial number and date of the complaint; the name and address of the complainant or the location of the condition complained of; and the date of transmittal to the district office for investigation and report. When the nature of the complaint clearly indicates an omission or neglect on the part of a service contractor, the main office should send notice of the complaint simultaneously to both the district highway office and the contractor assumed to be responsible. Upon its receipt at the district highway office, the complaint should be registered and issued to an inspector for investigation and report. If a service complaint should be originally received at the district highway office instead of at the main highway office, the complaint should be investigated as usual, and in the meantime, the main office should be advised of its existence and a serial number assigned to it. After being investigated and reported upon by the inspector and the findings or recommendations approved by the district assistant engineer, the complaint form should be forwarded to the main office, where the entry in the service complaint register should be closed out by entering the date of the complaint form's return.

Tickler File. One of the principal and best means for heads of departments and divisions to control the performance of periodical functions and inspections, and of insuring that proper attention is given to deferred and prospective duties, is a tickler or follow-up system. The responsibility for operating such a system should in all cases be assigned to some one definite person.

The STYLE OF FILING CABINET best adapted for tickler purposes consists of twelve drawers, one for each month of the year; and each drawer having a sub-division or index pocket for each day of the month. It is also desirable to provide special compartments in which may be filed such data as requests for forthcoming reports or publications, work to be included in the next letting of contracts, specification amendments, etc. These filing compartments should be of such a size as to enable the tickler copies being filed flat.

USE OF TICKLER FILE. For use in the tickler file, a memorandum or a copy of the involved correspondence made on a tickler filing copy sheet should be used. This tickler filing copy should be of a color distinct from that of the sheets used for general

correspondence, preferably pink, and should indicate the date upon which the matter is due for attention, and the name of the person who is to report upon it or to whom it should be referred. These tickler copies should be filed chronologically. Each morning the person in charge of the tickler file should notify those persons against whom are filed ticklers becoming due on that date, of the nature of the matters to receive attention and if possible secure from them the necessary formal reports or other acceptable assurance that the matter will be given proper attention. The tickler copy should not leave the possession of the person in charge of the file, but should be retained in the file as a further check to insure the actual performance of the indicated duty, either on the date first noted, or at a definite future date, if it is not possible to conclude the matter on the date on which it is due.

12. Permits and Licenses

Classification of Permits. In order that the field covered by the issuance of permits coming under the jurisdiction of the Permit Division of a large municipal highway department may be understood in detail, the four following general classifications are given, together with the natures of the privileges and concessions included in each:

1. Use, including the use of highways by electric railway cars, automobiles, motor-trucks, horse-drawn vehicles and barrows and for the transportation of steam-propelled machines, the moving of buildings and other loads of unusual weight or traction requirements.
2. Occupations, including the temporary occupation of highways by stored materials or structures incident to building or other construction work.
3. Encroachments, including the permanent occupation of space within the lines of a highway, either on or below or above the surface, including tunnels, vaults, awnings, marquise, private bridges, overhead pipe or pole, and wire lines, and portions of buildings.
4. Openings, including the opening of highways for the purpose of installing, overhauling or repairing mains, services, sewers, conduits, vaults, car tracks and appurtenances.

Administration of a Permit Division. The first step in the organization of a Permit Division should be the assignment of a supervising engineer to assume full and exclusive control of the division under the direction of the administrative office of the Highway Department. Any necessary modifications should, however, be made to suit the conditions existing in a state, county or township organization. In the case of a state or county department, for example, it would possibly be necessary to issue permits from the district offices, and if desirable this could also be done in a large municipality. This should be followed by the compilation of a record of paved highways under maintenance guarantee, and a complete record of the character of pavement existing on all streets and roads. To facilitate reference, the records of pavements under maintenance guarantee should be typewritten on cards which should be filed in a visible filing cabinet. On each individual card record should be noted all the information required for use as a guide in issuing a permit. The record of pavements not under guarantee may be made in the form of a map indicating by colors the several characters of pavement. To complete the record and also insure that no permit may be issued for the opening or occupation of a highway on which new pavement is about to be laid or is in course of construction, a copy of the contractor's notice to proceed with the work should be sent by the Engineering Division to the Permit Division where it should be placed on file as a temporary ready reference and destroyed upon receipt of the permanent record, prepared at the completion of the work. An adequate

and efficient set of forms, a modern filing system and an effective follow-up or tickler system should also be installed. Any forms or practices not required by existing legislation and for which no good reason can be assigned for their continuance should be discontinued.

The Forms and Filing Devices of a Permit Division should consist of the following:

1. Pavement record cards; upon which are recorded the character of the pavement and other essential data concerning each block of highway pavement under maintenance guarantee.

2. A record or map indicating by colors the earth roads and the character of pavement on each street or road not under maintenance guarantee.

3. Application forms; upon which the prospective permittee prepares a formal application to open or occupy a highway, or to erect an awning.

4. Permit issuance notification forms; originated in duplicate and by means of which the district officers are notified of the issuance of permits and a tickler copy is retained in the Permit Division.

5. Permit registers; to be used by the district officers to maintain a record of the receipt and disposition of permit notification forms.

6. Notice to the division engineer of the failure of the district office to make within a reasonable time a final report on outstanding permits. The use of this form is based upon the assumption that a division engineer may have under his supervision a number of district offices.

7. A set of four loose-leaf binders for each district office, one binder being used respectively for each of the four kinds of permit register sheets; and numerically indexed active file and a highway name indexed inactive file for the filing of permit notification forms in the Permit Division.

Permits for Opening a Highway. The system for the control of permits involving the opening of a highway for the repairing of existing sub-structures, or the installation of service connections or other minor sub-structures should be as follows: The applicant should prepare a formal application (Form G) indicating the name and address of the permittee, the location for which the permit is asked, and the nature of the work to be done under the permit. This application should be presented to a permit clerk who should immediately refer to the record of highway pavements. If no maintenance guarantee exists, or it has expired, and there is no other objection, the

BUREAU OF HIGHWAYS DEPARTMENT OF PUBLIC WORKS PHILADELPHIA	APPLICATION FOR PERMIT TO OPEN HIGHWAY PAVEMENT	APPLICATION NUMBER

CHIEF, BUREAU OF HIGHWAYS,

SIR:

.... hereby

make application for permit to { break / tunnel } highway

to { install water service pipe / repair water service pipe / install sewer lateral / repair sewer lateral } at.............

....

....Street

Name of Applicant..........................

Address..................................

Form G

application may be approved by the permit clerk and the permit issued. If, however, the guarantee has not expired, the application should at once be referred to the supervising engineer who should consult the data on record relative to the previous notification of abutting property owners of the necessity of installing any sub-surface connections within a certain definite number of days prior to the starting of the construction of the guaranteed pavement. The supervising engineer from his knowledge of the conditions governing each specific case either approves the application or disapproves it for sufficient reasons. In the case of public utility corporations the applicant should file either a release from the guarantor of the pavement stating that the opening to be made will not affect the guarantee, or a certified order upon the guarantor to restore the pavement to its original condition. If the application is approved, upon the payment of the regular charge, if any, for the restoration of the pavement, the permit should be issued and should be valid for a stipulated period of time as indicated thereon.

Permits for the Temporary Occupancy of Highways for storing building materials should be governed by the following procedure during issuance: The applicant should pay the regular stipulated fee to the Permit Division, and after signing his name and address on the duplicate permit retained in that Division, the original permit should be issued to him.

Awning Erection Permits should be issued according to the following procedure: The applicant should fill in and present to the Permit Division an application form. This application should be numbered and sent to the proper district office, where an inspector should be assigned to investigate the conditions existing at the location indicated in the application, and upon the return of the forms, with the approval of the district assistant engineer, the applicant should be notified to pay the regular stipulated fee whereupon the permit should be issued.

Details of Operation During Life of Permit. In detail the permit forms must vary according to the purpose for which they are issued, but in general all should contain a serial number, date and nature of the permit, the name of the permittee, the location for which the permit is issued and period of the permit's validity. At the time of the issuance of permits, the permit clerk should fill out a permit notification form (Form H) in duplicate, on which should be indicated the serial number, the date, the nature of the permit, the name of the permittee, and the location for which the permit is issued.

District Assistant Engineer

Form H

The original copies of the permit notification form should be forwarded to the respective assistant engineers of the districts in which the permits apply, and the duplicate copies should be filed in the active permit notification file of the Permit Division, numerically by serial number, under the date on which the original notification is to be reported on and returned from the district office.

Upon the receipt of the permit notification forms at the district offices there should be recorded from them in the proper District Permit Registers the following data: The serial number, the date of issue and receipt, the name of the permittee, the location for which the permit is issued, the date of the permit's expiration and the character of the pavement involved. Four Permit Registers should be maintained, one each for openings in highways, occupation of highways by building materials, erection of awnings and miscellaneous permits, respectively. These registers should be gone over daily, thus obviating the possibility of inspections being omitted or neglected for an unreasonable length of time.

Where in regular practice the pavement restoration is performed either by department forces or under a contract, the district assistant engineer should issue the necessary restoration orders and follow them up to insure that the work is performed within a reasonable time. Those permittees who do not pay the stipulated fees, but who are authorized to restore the pavement themselves, or thru an order given to a contractor, should notify the Highway Department when the repairs are to be made so that inspectors can be assigned to supervise the work. If prior to, or at the time of the expiration of the permit's period of validity, which for example in the case of a pavement opening may be 2 weeks, and 1 month where the highway is occupied by building material, etc, conditions become normal by reason of the restoration of the opened pavement or by the removal of permitted obstructions, etc, the final report on the permit notification form should be endorsed by the inspector and approved by the district assistant engineer, and after the entry in the district Permit Register is closed out by the insertion of the date of the final inspection and the inspector's name it should be returned to the Permit Division.

A report should be made at the end of each month to the Permit Division by the district assistant engineers showing all permits not finally reported on and giving the reasons therefor. The permit clerk should check these reports with the active permit notifications on file, and set back under the proper dates, those on which definite promises are given of future reports or repairs to be made either by a permittee, contractor or department forces. If the repairs are not made as promised, a notice should be sent to the division engineer notifying him to give the matter his personal attention and submit a report to the Permit Division within 5 days, and the permit notification form should be set back that number of days and called to the attention of the division engineer if he fails to make his report within that time.

In cases where the validity of a permit has expired and the necessary restorations have not been made prior to the time at which the monthly reports of overdue permits are forwarded to the Permit Division by the several district offices, the promise to finish should not exceed 5 days, unless there are some exceptional circumstances that will warrant an extension of time. In cases where it is necessary that repairs be made within this stipulated period of 5 days, and the Permit Division has not been notified by the district office that the repairs have been made, the permit clerk should get in telephonic communication with the proper district office and ascertain if the repairs have actually been made, as the district office may not have had sufficient time in which to notify the Permit Division. If such repairs have not been made, the Permit Division should issue a written notice to the proper responsible individual or corporation demanding that repairs be made within 48 hr. A copy of this notice should be sent to the proper district office, and the permit notification should be set back for 3 days. If the repairs are not made within 48 hr, the district assistant engineer should cause the repairs to be made under the general repair contract or by department forces, and render an accounting of the cost of the repairs to the Main Office where arrangements should be made to proceed to collect the amount from the responsible party or the surety. The permit notification form should also be forwarded by the district office at the same time with a proper endorsement of the facts of the case. In all cases the permit clerk should, prior to the return of the original copy, note on the reverse side of the duplicate copy of the permit notification from the various steps taken to have restorations made. Upon the return of the original permit notification forms to the Permit Division, the

duplicate copies should be destroyed, and the original copies should be filed alphabetically by location in the inactive file.

The issuance of permits for encroachments and for the use of the highways for the purpose of transporting loads of unusual character or weight should be based upon an investigation of the conditions prevailing in each specific case.

13. Contract Procedure

Purpose. If the actual physical work of highway construction and maintenance is to proceed in an orderly manner, it is necessary that the office procedure relating to the advertisement of proposals and the preparation of contracts should be thoroly systematized. A modern system of contract procedure should have the following purposes in view:

1. The establishment of a complete, concise, flexible and easily interpreted progress record of all work performed by contract, covering in detail and in orderly sequence all the events from the authorization of the work to its physical completion.
2. The provision of data relative to physical, legal and financial conditions by which may be determined the proper time for advertising for bids and for placing work under contract.
3. The installation of office equipment and procedure in which would be required a minimum of engineering and clerical labor in the operations preliminary to the beginning of the physical construction work.
4. The centralization of the control of operations, procedures and conditions having to do with the advertisement of proposals, the preparation of contracts and the order in which the work is to proceed.
5. The provision of data from which any desired character of report concerning contract work could be readily compiled.

Classification of Contracts. With reference to their period of effectiveness, contracts may be divided into two general classifications, namely, annual contracts and job contracts. The annual contracts remain effective only during the indicated calendar year, while job contracts remain in force until the provisions of the contract are fulfilled and accepted. In general, job contracts usually include highway and special construction and maintenance work, while annual contracts include service work such as street cleaning, the collection and disposal of ashes, rubbish and garbage, sprinkling, team hire, etc. While all contracts necessarily follow the same fundamental procedure, the several details of the procedure vary according to the needs of the individual contract. The detailed procedure for highway construction contracts, however, covers all of the possible details for all kinds of contracts, and in view of this fact the description of the contract procedure will be confined to the details applicable to highway construction. For contracts of a nature requiring the use of a lesser number of procedure details, the identity of the several details actually required will be obvious.

Philadelphia Bureau of Highways Contract Procedure. The details of contract procedure as employed in 1917 while the author was Chief of the Bureau of Highways and Street Cleaning of Philadelphia are as follows:

Operating Equipment. To provide for the efficient operation of the contract procedure, the following forms, filing devices and instructions were provided: (1) Contract record sheets, one each of distinctive colors for grading, paving, repaving, surfacing, resurfacing and miscellaneous contracts respectively; (2) schedule of bid forms, one each of distinctive colors for the records of the Bureau of Highways, the Department of Public Works and the City Controller, respectively; (3) certified check and contract award record forms, of distinctive colors, two for the records of the Bureau of High-

ways and one for the records of the Department of Public Works respectively; (4) contract ledger forms, (5) daily progress report postal cards; (6) inspectors' contract work certification; (7) printed form letters for every letter of a fixed form comprising part of the contract procedure; (8) written instructions explaining in detail the operation of the contract procedure; (9) suitable filing cabinets, indexes and loose-leaf binders.

Arrangement of the Contract Record Files. The contract record files, one of which is maintained for the work under the supervision of each of the two division engineers are arbitrarily divided into several logical sub-divisions with the idea that a contract record shall be progressed thru the several successive sub-divisional units of the file as rapidly as the governing conditions would warrant, and from the position currently occupied by the record in any one of the several sub-divisions, could be based the intelligent administration of the subsequent operations of the procedure. The several sub-divisions of the procedure are as follows:

1. AUTHORIZED. In this sub-division the contract procedure has its origin, a record being prepared for each parcel of work immediately after its authorization by ordinance of City Councils. The records in this division are further sub-divided according to the character of the work authorized, as follows: (1) Grading, (2) Paving, (3) Repaving, (4) Surfacing, (5) Resurfacing, (6) Miscellaneous.

2. PROPOSAL ADVERTISEMENT PREPARED. In this subdivision is included the work for which drawings, specifications and proposal forms have been prepared, and will be included in the next advertisement.

3. UNDER CONTRACT. In this sub-division is included any of the work in the several following stages of the procedure: (1) Proposals advertised, (2) contract awarded, (3) contract ordered executed, (4) contract executed, (5) notice issued to contractor to proceed with the work.

4. FINISHED. This sub-division includes all the work that has been physically finished. The records in this division are filed according to the year in which the work is finished.

5. TO BE REJECTED. In this sub-division is included the work for which bids are in course of rejection or the contract is in process of annulment.

6. INACTIVE. This sub-division constitutes the final disposition of records which have been superseded by revised records by reason of the passage of modifying authorization ordinances; the rejection of bids, or the annulment of contracts.

The Origination of the Contract Record. Upon the receipt of a certified copy of the authorizing ordinance, a comparison is made of this ordinance with previous ordinances and any conflictions discovered are noted for adjustment, after which a contract record sheet for the indicated character of work (Form I) is originated and the following data supplied: The name of the highway and the limits of the proposed work; the ordinance date; the character of the existing, if any, and of the authorized pavement; and the numbers of the highway division and district, the survey district and the ward in which the proposed work is located. There is then determined the status of the several following legal and physical conditions. For all classes of highway construction, the Bureau of Surveys is requested to certify to the legal width of the highway; to its being on the city plan and legally opened; and also to the status of any existing or proposed sewers, sewer laterals, manholes and inlets. For paving work only the Department of Revision of Taxes is requested to indicate the tax rate applying to properties abutting on the length of highway involved. The reports submitted in answer to these requests are recorded on the contract record.

DRAWINGS AND ESTIMATES. If the drawings and estimates for the proposed work are not already on file, a set of four copies is ordered from the Bureau of Surveys. Upon the receipt of the drawings and estimates a serial filing number is assigned to two of the sets, and is also recorded on the corresponding contract record. The serial-numbered set is folded or rolled to a standard size and filed numerically. Two sets of the drawings and estimates are forwarded to the district assistant engineer, one copy being intended for a district office record and the other copy being for subsequent issue to the inspector assigned to the supervision of the work.

Conditions Governing Advertisement. The availability for advertising of proposals for performing miscellaneous work and supplying materials and services is governed by the status of conditions especially applicable to each specified situation. In general,

ENGINEERING CONTRACT RECORD

DIVISION		ENGINEERING CONTRACT RECORD		CLASSIFICATION OF WORK	INDEX
DIST. HIGHWAY		FROM	TO	PAVEMENT / EXISTING / PROPOSED	
DIST. SURVEY		CONTRACTOR NAME	ADDRESS	SURFACE	
WARD		SUB-CONTRACTOR NAME	ADDRESS	GUTTERS / TRACKS / BASE

AMOUNT CERTIFIED CHECK	AMOUNT PLACED ON CONTRACT: TOTAL			CITY		
AMOUNT PENAL BOND	CITY			ASSESSABLE		
	ASSESSABLE			FINISHED DURING YEAR		

Form I

the principal governing factors are, a need for the work, materials or service and the existence of the necessary funds with which to pay therefor. Before a parcel of highway construction work is considered as being available for advertising it is necessary that there should be a demand for the work and that no conditions should exist that would interfere with or prevent the prompt physical prosecution of the work, and, therefore, the status of the following governing conditions should be as indicated in Table III.

Table III

Governing Conditions	Character of Work					
	Grading	City Street			Country Road	
		Paving	Re-paving	Re-surfacing	Sur-facing	Re-surfacing
Authorizing ordinance	Yes	Yes	Yes or No	Yes or No	Yes or No	Yes or No
On city plan	Yes	Yes	Yes	Yes	Yes	Yes
Legally opened	Yes	Yes	Yes	Yes	Yes	Yes
City tax rate	No	Yes	No	No	No	No
At confirmed grade	No	Yes	Yes	Yes	Desirable	Desirable
Sewer constructed	No	Yes	Yes	Desirable	Desirable	Desirable
Plan and estimate	Yes	Yes	Yes	Yes	Yes	Yes
Necessity for work based upon an investigation	Yes	Yes	Yes	Yes	Yes	Yes
Funds available	Yes	Yes	Yes	Yes	Yes	Yes

Yes indicates an absolute necessity that conditions must exist as indicated.

No indicates that it is not necessary that indicated conditions exist.

Yes or No indicates that the existence of the necessity is dependent upon the specific provisions of ordinance appropriating the funds.

Desirable indicates a desirability, but not an absolute necessity, that indicated conditions must exist.

Preparation and Advertisement of Proposals. To insure the efficient operation of the procedure for the preparation and advertisement of proposals for highway work the following forms, equipment and methods were provided:

1. Proposal estimate forms; one distinctive form for each of the four general classifications of highway construction work, each form containing all of the fixed data likely to be used and providing spaces for the insertion of the necessary variable data.

2. Schedule of standard proposal item terms; which provides a complete and logically arranged classified summary of all of the fixed and variable standard terms likely to be used in the preparation of proposals for highway construction work.

3. Proposal or bid forms; one distinctive form for each of three classes of proposals. Two of the proposal or bid forms also contain schedules of fixed prices for every character of contingent work likely to be encountered.

4. Advertised work estimate forms; on which is indicated the limits, quantity and estimated cost of all work proposed to be advertised.

5. Advertised work schedules; which indicate the character and geographical limits of each parcel of work advertised and are issued to prospective bidders to serve as a guide in their pre-inspection of the sites of the proposed work.

6. Proposal envelopes; which are issued to prospective bidders for the purpose of enclosing in them their proposals.

7. Report of low bidders and prices; which facilitates the preparation of reports to the Chief of the Bureau and the press.

8. Specimen sets of the proposal forms, specifications and drawings for each parcel of advertised work; all of which are filed in convenient, readily accessible and properly indexed files for the inspection and information of prospective bidders.

9. Special filing cabinet; in which proposals awaiting distribution to prospective bidders are filed in a readily accessible manner and are properly indexed according to the letting date and schedule letter.

10. Improved method of proposal form distribution by which each prospective bidder is furnished with a complete set of proposal forms for each schedule applied for.

11. A hectograph duplicating device by which the propcsal forms are duplicated, thereby dispensing with the handwriting or typewriting of proposals and subsequently checking them for accuracy.

Preparation of the Proposal Estimate. As soon as the several governing conditions become favorable, the original office copy of the proposal is prepared in ink handwriting on a proposal estimate by the division engineer and checked by his assistant or vice versa. The four kinds of proposal estimate forms were intended to be used as follows:

Form Number	Character of Work to be Used for		
1-A	Grading		
1-B	Paving with		Asphalt Vitrified block Granite block Wood block
1-C	Repaving Resurfacing	with	Asphalt Vitrified block Granite block Wood block
1-D	Surfacing Resurfacing	with	Concrete Water-bound macadam Bituminous material

In general, on each of these forms is recorded the following data: Division (number); location, street, (name) from, (name) to, (name); letting date, (date); certified check, (amount); days allowed for completion of work, (number); estimate of work to be performed, (quantity and character); notes and special requirement, (stated explicitly and briefly, if any). Any printed data on the proposal estimate forms that it is not desired to have appear on the proposal forms is stricken out.

Location of Proposed Work. The location is expressed in a concise manner and entered on the contract records. Numbered streets are indicated by numerals. The highway name need not, however, be followed by street, avenue, road, etc, except where such a designation is absolutely required to distinguish the highway from another having a similar proper name. Numbered street designations should be followed by the suffix st., nd., rd., or th., as may be required. When a highway is bounded by two numbered streets, the lower should precede the higher number. When two or more highways are grouped into one proposal, the named streets should be arranged alphabetically, followed by the numbered streets arranged numerically.

Letting Date. The date of the letting is set for a date at least 11 days after the date of the first insertion of the advertisement in the newspapers. Except where absolutely necessary, lettings do not take place on a Mon. or Sat.

Certified Check. The amount of the certified check is made equal to 2.5% of the estimated cost of the proposed work, and should always be expressed in the nearest round figure which is a multiple of $5. For estimating purposes the figures given in the schedule of fixed prices for contingent work should be used.

Time Allowed for the Completion of Work. In fixing the period of time allowed for the completion of a parcel of work, careful consideration is given to the desirable or necessary speed for the prosecution of the work as governed by actual necessities and its influence upon the probable cost. In grading, especially where rock is to be excavated, or it is permissible to use ash filling and there is no necessity for hurrying the work, it is generally possible to obtain lower prices by lengthening the time limit.

In every instance a fair number of consecutive working days is allowed based upon the following considerations:

1. The period of time within which it is necessary that the work be finished as governed by the dependence of proposed subsequent work and of the necessities of public convenience.

2. The probable influence of the period of time allowed upon the cost of the work.

3. The physical possibilities of performing the work, such as the availability of materials and equipment; the conditions under which the work must be prosecuted;

and the average contractor's probable economical capacity to perform the respective classes of work.

4. The predominance of any specific class of work that would exclusively influence the time required for the performance of the entire parcel of work.

5. The study of plotted curves or other compiled data relative to the average quantities of work performed and the time allowance on previously performed work of a similar character.

For the purpose of definition, the use of such terms as week, month, or year are omitted in favor of the uniform unit of consecutive working day, which includes all days upon which the contractor may properly be expected to, or upon which it may be physically possible to work and excludes Sundays, legal holidays and such other days during which the weather conditions make it inadvisable or impossible to perform work. For extensive operations, such as boulevard construction and park development, it is absolutely necessary that very careful consideration be given to all of the known or probable governing conditions. On straight highway construction work, such as grading and pavement construction, the determination of proper time allowances presents a less complicated problem and may to a considerable extent be based largely upon approximate average values of plant output and the economical number of gangs and men per gang and equipment for hauling obtaining on previously performed work. The notice to the contractor to proceed with the work should allow him sufficient time to assemble his plant before the time is counted against his contract. Ten days is considered to be ample time to allow in which to assemble the equipment, and deliver the materials and start actual work, in the case of ordinary grading and pavement contracts, but it would not be sufficient time in extensive operations, where considerable plant equipment is required. On all work except grading a further allowance of 5 days per entire job is made in the total time allowed to compensate for the time required in the changing of equipment and gangs, cleaning up, etc.

Grading. The general classification of grading may be sub-divided into the distinctive items of earth excavation, rock excavation and filling. The economical limit for performing work by hand is governed by a number of conditions and will probably vary between 5 000 and 15 000 cu yd to meet these conditions. In every case the advisability of performing the earth excavation by hand or by shovel should receive careful consideration. If the shovel method is determined upon, the average depth of the cut and the number of shovels to be operated should also be considered. In connection with rock excavation, the character of the rock and the possibility of the employment of light or heavy blasting should be considered. With respect to filling, the availability of the filling materials should be known with a reasonable degree of certainty. Easily available material may be considered to be easily transported material located within 1 mile or less of the work, or clean ashes being collected from the neighboring territory. Based upon the foregoing considerations and the minimum output of a single plant equipment of average capacity for the class of work and the average number of workmen employed on a job by a contractor conducting several similar operations simultaneously, the following approximate average values are given:

Table IV.—Daily Grading Capacities

Nature of Work		Average Depth in Ft	Cu Yd Allowed per Day
Earth excavation	Hand method	Any	100
	Shovel method	5	250 per shovel
		7	350 per shovel
		9	450 per shovel
Rock excavation, any method		Less than 5	90
		5 and less than 10	100
		10 and over	105
Filling	Material easily available	Any	175
	Material not easily available	Any	125

Pavement Construction. The principal governing factors in the case of pavement construction are the time required for the construction and setting of the cement-concrete base and the setting of the grouted block joints. Consideration must also be

given to the necessity for changing the several types of equipment necessary for the performance of successive stages of the work. It should also be assumed that on work having an area of approximately 8000 sq yd or less, the construction of the surface course will not proceed until the entire concrete base has set. Considering these conditions and assuming 1000 sq yd as a unit area, the following approximate values are used as a basis for tentative calculations:

Table V.—Time Allowances for Initial Thousand Square Yards of Indicated Operations

Nature of Work	Days Allowed
1. PREPARATORY WORK.	
Earth subgrading and rolling on original work	2
Removal of existing water-bound or bituminous macadam pavement including broken stone or telford base, subgrading and rolling	4
Removal of existing sheet-asphalt or block pavement, including broken stone, bituminous or gravel base, subgrading and rolling	3
Removal of existing sheet-asphalt or block pavement from a concrete base	1
Preparation (cleaning, scarifying and shaping) of existing water-bound macadam for resurfacing	1
2. BASE COURSE CONSTRUCTION.	
Cement-concrete, 4, 5 or 6-in base course	3
Broken stone, 3 or 5-in base course	2
Telford, 8-in base course	3
3. SURFACE AND BINDER OR CUSHION COURSE CONSTRUCTION.	
Sheet-asphalt, 2-in surface and 1-in binder courses	2
Asphalt paint coat application and drying	1
Bituminous, 2-in surface course	2
Granite block surface and 1½-in sand cushion courses, including grouted or bituminous joint filling	5
Vitrified block surface and 1-in sand cushion courses, including grouted or bituminous joint filling	3
Wood block surface and 1-in mortar cushion courses, including sand joint filling	2
Water-bound macadam, 3 or 4-in surface course	2
4. SETTING OF WORK.	
Setting of cement-concrete base course at least	3
Setting of grouted joints in granite block pavement	7
Setting of grouted joints in vitrified block pavement	7
Setting of mortar cushion in wood block pavement	2

By interpolating these elemental time allowance values, it is possible to readily determine the proper total time allowance for the initial unit of a 1000 sq yd of any classification or character of work as based upon what may be considered fair average daily performances, using one concrete mixer and single equipment thruout.

In the following schedule are enumerated for convenience of reference the several classifications and characters of work most generally encountered in general highway construction.

As a general rule, it will not be necessary to allow extra time for the performance of the minor items or miscellaneous contingent work as this work is generally done simultaneously with the performance of the principal items of the work. When the area of work exceeds 1000 sq yd the full time as indicated in Table V for each successive process or operation should be allowed for each additional 1000 sq yd or fraction thereof, except the time allowed for the setting of cement-concrete and grout joints and for the changing of equipment, etc, should be included but once. If it is necessary or desirable that two or more plants be operated, then the total area of the work should be divided by the proposed number of plants and the time allowed for the entire contract should be based only upon the quantity of work to be performed in conjunction with one plant, as each additional plant will be assumed to operate simultaneously and at the same rate of progress. In cases where street railway tracks exist, or it is required to maintain the highway partially open to traffic, and it is, therefore, necessary that the pavement be constructed in two or more separate runs, extra time should be allowed to compensate for these unusual conditions. In general where there are any considerations that might mitigate against the performance of the

work within the time fixed for the several classes of work in the foregoing schedule, an arbitrary number of extra days, based on the judgment of the engineer should be added to the time limit. The time limit, except where there are other more important considerations, should in all cases be based largely on the average contractor's economical time limit, and this will vary in different localities. After the total time to be allowed is finally determined upon, if the number of days allowed is not a number divisible by five it is desirable as a matter of policy to express this number of days in the nearest higher round number of days which is a multiple of five.

Table VI.—Time Allowances for Initial and Additional Thousands of Square Yards of Indicated Pavement Constructions

Classification and Character of Work		Days Allowed per Unit of a 1000 Sq Yd	
		Initial	Additional
1. Paving or New Permanent Pavement.			
a. Original permanent construction on unimproved and newly graded highways:			
Sheet-asphalt	Base, binder or cushion and surface courses	15	7
Granite block		28	10
Vitrified block		23	8
Wood block		17	7
b. Displacing existing macadam pavement:			
Sheet-asphalt	Base, binder or cushion and surface courses	17	9
Granite block		30	12
Vitrified block		25	10
Wood block		19	9
2. Repaving or Replacement of Permanent Pavement.			
Displacing existing permanent pavements not on a concrete base with permanent pavements having a concrete base:			
Sheet-asphalt	Base, binder or cushion and surface courses	16	8
Granite block		29	11
Vitrified block		24	9
Wood block		18	8
3. Surfacing or New Semi-Permanent Pavement.			
Original semi-permanent construction on unimproved and newly graded roads:			
Water-bound macadam with broken stone base	Base and surface courses	11	6
Water-bound macadam with telford base		12	7
Bituminous macadam with broken stone base		11	6
Bituminous macadam with cement-concrete base		13	5
4. Resurfacing or Restoration Work.			
a. Replacing existing semi-permanent or macadam pavements:			
Water-bound macadam on existing base	Surface course base and surface course.	8	3
Bituminous macadam on existing base		8	3
Bituminous macadam including cement-concrete base		14	6
b. Replacing surfaces of existing permanent pavements on existing cement-concrete base:			
Sheet-asphalt	Binder or cushion and surface courses	10	5
Granite block		23	18
Vitrified block		18	13
Wood block		12	7
Bituminous macadam		10	5

ESTIMATE OF WORK TO BE PERFORMED. All estimate of quantity items are expressed in the manner and in the terms indicated in the schedule of standard proposal item terms. The proposal estimate forms each contain a complete list of such items as are likely to be included in the character of work covered by that specific proposal estimate form. All fixed data is printed on the form, while all variable data has been omitted and blank spaces provided for the insertion of the required standard terms. Preceding each item on the proposal estimate forms are index numerals which indicate where, in the schedule of proposal item terms, the standard variable terms may be found. These standard variable terms are indicated on the schedule or proposal item terms in capital type and are enclosed in parentheses.

NOTES AND SPECIAL REQUIREMENTS. All proposal data is clearly and briefly expressed but is not abbreviated. When payment is to be made from an anticipated appropriation, the following provision is used. This work is advertised subject to future appropriation by Councils. When it is obvious or probable that excess grading may be required the following provision is used: The cost of all grading that may be required in connection with this work shall be included in the price bid for paving, or other work as indicated.

Preparation of the Original Proposal or Bid Forms. All proposal or bid forms are typewritten in hectograph ink. The data shown on the proposal estimate forms is transcribed to the proposal forms exactly as indicated. If any of the data is obviously or apparently incorrect, the matter is reported to the person who originated it. All deviations from the standard specifications and any special requirements are noted on the proposal estimate forms and approved by the division engineer. If these notes are so extensive that their indication on the proposal or bid form would be impracticable, and it is therefore necessary to adapt or revise the existing standard specifications to meet the requirements of the prospective work, the following clause is entered on the proposal or bid form following the estimate of quantities: Work under this contract is to be performed in accordance with the standard specifications, including corrections as noted, of the Bureau of Highways for (year) marked Specifications for the letting of (date). It is further understood and agreed that this proposal becomes a part of said specifications and further that if any conflict exists between this proposal form and the specifications, the terms of the proposal form shall govern.

The specific kind of proposal or bid forms used for any parcel of work is governed by the character of work as follows: Grading streets or roads, paving city streets, repaving or resurfacing city streets, surfacing or resurfacing country roads, other miscellaneous work, material or service. Whenever possible to do so, all the data is written on the first page of the proposal or bid form so that the hectographed copies may be prepared in one operation.

PREPARATION OF THE HECTOGRAPHED COPIES OF THE PROPOSAL OR BID FORMS. The number of hectographed copies of the proposal or bid form for each specific parcel of work to be prepared is governed by the probable demands of prospective bidders and the needs of the contract procedure after the contract is awarded.

PREPARATION OF THE COST OF WORK ESTIMATE. When the quantity of work to be advertised is definitely determined upon, a report is prepared, giving separately for each division the following data: Character of work, classification of work and character of materials; location of street, name, from .... to ......; quantity, square yards of pavement or cubic yards of grading; estimated cost, lump sum figures for the total cost and the cost to the city for each classification and character of work. These reports are compared with the appropriation ledger to insure the existence of the necessary funds and are finally approved by the Chief Engineer as to the quantity and character of work to be advertised.

CHECKING. The checking is carefully and thoroly done and any necessary alterations made in red ink, and the original data stricken out but not erased. It is especially important that the data shown on the proposal estimate form be absolutely accurate and expressed according to the standard methods and terms before being transferred by typewriting to the proposal or bid forms. The typewritten copy of the proposal or bid form is carefully checked with the original handwritten copy of the proposal estimate form. The responsibility for the accuracy of this final checking should be centered in one person. Spaces are provided on the proposal estimate form for the dates and initials of those persons preparing, checking and typewriting the forms. This data is supplied so that the responsibility for errors can be properly placed.

Preparation of the Advertisement Schedule. For each letting there is prepared an advertisement schedule in which each classification of work and character of pavement material or service is included in a separate lettered schedule arranged alphabetically. The standard arrangement is as indicated in the following specimen schedule, but when some of the enumerated classes of work are missing, only a sufficient series of letters, beginning with A, is used to indicate the schedules: Work advertised, date; bids to be received, date; drawing number, street, and location for each of the following schedules, A, grading, B, sheet-asphalt paving, C, vitrified block paving, D, granite block paving, E, wood block paving, F, sheet-asphalt repaving, G, vitrified block repaving, H, granite block repaving, I, wood block repaving, J, sheet-asphalt resurfacing, K, vitrified block resurfacing, L, country road surfacing, M, country road resurfacing, N, etc, other miscellaneous classes of work, materials or service. Of each advertisement schedule a sufficient number of copies should be hectographed to satisfy the requirements of the prospective bidders and the contract procedure.

Advertisement of Proposals. Proposals are regularly advertised three times in five local daily newspapers, one of which remains the fixed advertising medium for a period of 6 months. It is usually arranged that collectively advertisements appear in a morning newspaper, an evening newspaper and newspapers printed in German, Italian and Hebrew. When proposals for extensive work are advertised, and it is considered advisable to do so, the proposals accompanied by an estimate of the principal items of the work are published in several of the leading engineering journals. When the nature of the work or service included in any contract is such as to require, before bidding, an extensive study of the requirements of the proposed work, or to necessitate the formulation of plans on the part of the bidder, for the provision or establishment of an extensive plant or organization, a proportionately longer period of time is allowed to elapse between the initial advertisement and the submission of the proposals otherwise the time allowed varies between 10 and 15 days. Immediately after the work has been advertised there are noted on the contract record the date of the advertisement's first appearance in the newspapers and the date of the letting.

Distribution of the Proposal Forms. Complete sets of the proposal or bid forms for each schedule are enclosed in proposal envelopes which are stamped: Bureau of Highways, Schedule, (letter); Date of Letting (date).

A set of specifications for the work covered by the schedules is also enclosed. The number of sets of proposal forms to be prepared varies with the demands of the prospective bidders.

A specially designed filing cabinet has been provided in which the proposal forms enclosed in a schedule-lettered proposal submission envelope are filed according to the date of the letting and the schedule letter. Copies of the schedule of advertised work are distributed gratis to all prospective bidders. A complete set of specifications and proposal forms, properly indexed and bound respectively in separate loose-leaf binders, and a complete set of plans of the proposed work are placed at the disposal of the prospective bidders for their inspection and information. No charge is made for the proposal form, but a charge of 50 cents a copy is made for each set of printed specifications necessary to cover the class of work indicated on the proposal forms. Since the entire field of highway construction is covered in three sets of printed specifications, the maximum charge that will be made at any one time will likely not exceed $1.50, irrespective of the number of proposal forms issued.

Installation of Sub-Surface and Surface Structures. Immediately after the advertisement of the work, copies of the advertisement schedule indicating the characters and locations of the advertised work are prepared and issued to prospective bidders; the division engineers; the district assistant engineers; the contract record clerks; the district surveyors; the chief clerks of both the select and common branches of City Councils; and the Department of Law. Copies of these lists are also sent to the several municipal bureaus and public utilities, whose structures usually occupy highways, accompanied by a statement that the indicated work is about to be performed and requesting a prompt report of the status of existing and prospective conditions relating to surface and underground structures. This procedure insures the construction and repair, ahead of the construction of pavement, of all necessary structures, including sewers, sewer laterals, manholes and inlets, gas and water mains and services, electrical and telephone conduits and services, street lighting and street railway tracks, and any other street structures.

In response to these notifications the municipal bureau and public utilities will certify either that all necessary work has been finished and thereby release the street in so far as their requirements are concerned, or submit a statement of contemplated work, together with the period of time estimated for its completion. Releases are considered as final reports for the conditions reported on and all other reports are considered as merely provisional, but both classes of reports are recorded on the contract record in order to provide an up-to-date summary of the exact status of the sub-surface and surface structure situation. On the first of each month, in cases where a final report or release has not been received, a tickler statement is sent to each of the several municipal bureaus and public utilities showing the streets for which their respective releases have been requested but not received.

Simultaneously with the advertisement of all work except grading, the district assistant engineer in whose district the proposed work prevails is also requested to report upon the condition of the curbing. Where the installation or resetting of curbing is required the district assistant engineer serves on the tenant of the abutting property a notice requiring that the work, such as is indicated, be finished within 30 days. If at the expiration of 30 days the necessary work has not been done a further notice, demanding that the work be done within 48 hr is served, which, if unattended to, is followed by the issuance of an order on the contractor, having the annual curbing work contract, to do the necessary work and assess the cost against the abutting property owner. The district assistant engineer also serves on all tenants of property abutting on a street on which pavement is to be laid a formal notice to install any necessary sewer laterals or water, gas or electric services or other underground connections within 20 days. The district assistant engineer then submits to the main office a report showing the status of the curbing and also advises of the existence of any condition that would make it necessary to delay the physical prosecution of the highway construction work.

Submission of Proposals. A central locked proposal receptacle has been provided and placed in a location where it is at all times in view of the bidders and where the depositing of proposals cannot be observed. After 12 o'clock noon of the day of the letting, the proposal receptacle is publicly opened and the bids read aloud and also written on blackboards which are exhibited for the several succeeding days for the information of the public.

Contract Ledger. After bids are received there is also originated a contract ledger sheet. In addition to the principal items of information, there are also indicated on this form the dates and serial numbers of all estimates of finished work; the dates, warrant serial numbers and amounts of payments; the dates and amounts of any plus or minus adjustments; the unexpended balance of funds allotted to the contract; the date, percentage and amount of any cash deposit; and the dates of the release of the cash deposit and security bond.

Depending upon the status of the contract, the contract ledger forms are sub-divided into four separate divisions each of which is filed in separate binders as follows: (1) Bids received and contracts not yet awarded; (2) contracts awarded; (3) work finished and under maintenance guarantee; (4) work finished and not under maintenance guarantee.

Schedule of Bids. After the opening of the bids and the extension of the proposals, the schedule of bids form is prepared in triplicate in one operation, by typewriting, and one copy filed respectively in the office of the Bureau of Highways, the Director of the Department of Public Works and the City Controller. The schedule of bids form contains the schedule letter, the character of the work and the date of letting; the location, items, estimated quantities, unit and total bid prices for each particular parcel of work; and, the name and address of the bidders. From the data shown on this schedule are determined the successful or lowest bidders.

Statement for Newspapers. Immediately after the receipt of bids a statement is prepared for the several local newspapers indicating names of the streets upon which the proposed work will be done, the number of contracts and the estimated value of each class of work upon which bids were received. If it is possible to do so, the names of the low bidders are also given.

Report of Low Bidders and Prices. After the bids have been scheduled a report of the low bidders and prices is prepared. From this report a statement is prepared and submitted to the Chief of the Bureau giving the total quantities and unit bid

prices for grading and each character of pavement and its component parts; and the total amounts of the low prices for the work included in each schedule. Another statement is also prepared and submitted to the local newspapers and certain selected technical journals indicating similar data except for the addition of the names and addresses of the low bidders and the omission of the prices on the component parts of pavements.

Disposition of Certified Checks. A record of all the certified checks accompanying the proposals is prepared in triplicate on certified check and contract award record forms and two copies are forwarded, together with the certified checks to the office of the Director of the Department of Public Works. The duplicate copy is receipted and returned to the Bureau of Highways for file, while the original copy is retained in the Director's office and receipted by the bidders to whom the checks are returned. The check of the successful bidder is retained, however, until the execution of the contract.

Award of Contract. The triplicate copy of the contract award form is forwarded to the Director's office accompanying the schedule of bids and constitutes, after being signed by the Chief of the Bureau of Highways, the formal recommendation for the award of the contracts as indicated. If the recommended awards are approved, the triplicate copy is signed by the Director and returned to the Bureau of Highways, as the formal approval of the award. All three copies of this form indicate the character of the work advertised; the schedule letter and date of receipt of bids; the name and address of the bidders; and, the amount of their certified checks, and certain other procedure data which varies according to the specific function of each of the three forms. Upon the receipt of the approved contract award recommendation there is entered on the contract record the following data: the name and address of the contractor; the date of the award of the contract; the amount of the certified check; the items and estimated quantities of the work to be performed; the unit and total prices bid and the duration of the maintenance guarantee period.

Execution of Contract. Unless the governing conditions are such that the physical construction work can not be performed within a reasonable time, the Director of the Department of Public Works is asked to request the Department of Law to prepare the contract and have it executed. This request is accompanied by four copies of the proposal form and specifications applying to that particular parcel of work. These copies of the contract are ultimately disposed of as follows; one copy is given to the contractor, and one filed in the offices of the Mayor, the Department of Law and the Bureau of Highways respectively. From the requests for the execution of a contract is determined and entered upon the contract record the following data: The contract number and the date on which it is ordered executed; the amount of the penal bond; the amount of the funds allotted to the contract; the appropriation item number; the amounts of both assessable and non-assessable liabilty and the time allowed for the completion of the work. Upon the receipt from the Department of Law of an executed contract, the date of execution is recorded on the contract record, after which the contract is signed by the Chief of the Bureau of Highways, the Director of the Department of Public Works and the Mayor. Formal notice is sent to the Bureau of Highways of the date on which the contract is approved and signed by the Mayor and this is also noted on the contract record. Copies of the proposal form and, if necessary, the specifications are then forwarded respectively to the contractor, the district assistant engineer and the district surveyor.

Rejection of Bid or Annulment of Contract. When conditions arise that necessitate or make advisable the rejection of bids or the annulment of a contract there are noted on the contract record the date and the reason for the action that is recommended. The matter is referred by the Chief of the Bureau of Highways to the Director of the Department of Public Works for his approval and appropriate action. Upon notice of the Director's approval of the recommended action, the date of the approval is entered on the contract record, and also the date of the final disposition of the matter. When bids are rejected or a contract annulled, the contract record is noted, Inactive, see revised record, and, after being initialed by the respective division engineer, is filed in the inactive file. For every record so filed a new record is originated and noted Revised record. The revised record contains all the pertinent data shown on the inactive record.

Notice to Contractor to Proceed with Work. When a contract has been signed by the Mayor and all the requested releases for a specific street have been received and

there exists no other reason for further delaying the prosecution of the work, an undated notice to the contractor to proceed with the work is prepared, and placed in the Available Notices to Proceed file from which file the notices are removed by the respective division engineer as rapidly as the contractors' working capacity will permit and are issued by the Chief of the Bureau to the contractor. The date of the issuance of the notice to proceed is entered on the contract record. Copies of the notice to proceed are furnished to the following: The contractor, accompanied by a copy of the drawings; the district assistant engineer; the district surveyor; the Bureau of Water; the permit division of the Bureau of Highways and any municipal bureau or public utility which desires to do work that cannot reasonably be done in advance of the highway construction work. The necessity for this latter notice will be ascertained by reference to the notes on the contract record requesting it. If a notice to proceed is recalled, the above indicated bureaus or public utilities are notified of the fact and the date of its recall noted on the contract record. In general a notice to proceed is never issued until all structural work is finished. When there exists an urgent necessity for the issuance of a notice to proceed with a portion of the work prior to the completion of certain structural work, a statement of understanding and agreement accompanies the notice to proceed sent to the contractor by which the contractor agrees to defer the laying of pavement at the locations where sub-surface or surface structural work is in progress. Copies of this letter are forwarded also to the municipal bureau or public utility involved and the district assistant engineer.

Division Engineers' Progress Reports. On each fourth Monday morning, the division engineers submit to the Chief Engineer a statement of the status of all the work under contract in their respective divisions. These reports contain a record of the character and limits of the work; the name of the contractor; the status of the structural conditions and of the contract; and the dates, if any, of the issuance of the notice to proceed and of the starting of the work.

Inspectors' Daily Progress Report. For each day that the physical construction work is in progress the inspector supervising the work transmits to the main office a daily progress report (see Form J). This report indicates the character and limits of the work under contract; the character, quantity and location of the work performed;

FROM TO

WORK	PERCENTAGE FINISHED TO DATE 0 10 20 30 40 50 60 70 80 90 100	QUANTITIES OF WORK PERFORMED ON THIS DATE

DAILY PROGRESS AND FORCE REPORT ON CONSTRUCTION WORK	TOTAL HOURS OF WORK IN PROGRESS	INSPECTOR

Form J

the name of the contractor; the number and total hours of time for each class of labor and equipment; the total hours during which the work was in progress; the inspector's signature and the date of the report. These reports are in such detail that, if it is desired to do so, they may be used to plot the progress of the work on a progress map From the first report submitted there is entered on the contract record the date of the

starting of the work. After being inspected by the respective division engineers, the progress reports for each parcel of work are filed together chronologically.

Completion of a Contract. Upon the satisfactory completion of a contract, the district assistant engineer will certify the fact to the main office, and will also indicate on a separate report whether or not this work was finished within the time allowed for its completion. If the work has not been finished within the allowed time, the number of days of delay is reported and entered on the contract record. If there is no reasonable excuse for the delay the liquidated damages provided for are charged against the contract, after being approved by the division engineer, the Chief of the Bureau of Highways and the Director of the Department of Public Works. The number of days for which the damages are exacted is recorded on the contract record. The inspector or inspectors assigned to the supervision of contract work are required to execute for the period of their assignment a certification indicating that the work was performed in strict accordance with the drawings and specifications. Based upon this report of the completion of the work, the district surveyor is authorized to prepare final estimates and bills, and the date of the completion of the work is recorded on the contract record.

Final Estimates. Upon the receipt from the district surveyor of the final estimate and bill for the work performed the following data is recorded on the contract record: The actual quantities and cost of the work performed; the assessable, non-assessable and total liability; and the length in feet of the highway affected. All estimates are subject to the joint approval of the inspector assigned to supervise the work, the district assistant engineer, the division engineer and the Chief Engineer.

General Operating Instructions. The responsibility for the operation of the contract procedure is centralized and is under the supervision of the principal assistant engineer. The records are available for general use only on application to those in charge of the details and filing system and no individual records may be removed from the files. In general, the contract records are filed alphabetically, followed by numbered streets, filed numerically. The contract records are advanced thru the several divisions of the procedure as rapidly as conditions will permit, and a frequent check of the records in each division is made to insure that their progress is not unnecessarily delayed. All entries on the contract records are made in black ink, except data pertaining to assessable liability, which is made in red ink. Rubber stamps are used for entering data wherever their use will economize time or enable the data to be more rapidly interpreted. The date and serial registeration filing number of all data recorded is also noted on the contract record.

14. General Clauses in Specifications

The different activities of a highway department require that many specifications be written. It is desirable, in order to avoid misunderstandings and promote uniformity in practice, that all the general clauses of specifications used in a given department, and, if practicable, in all departments of a given state, county, township or municipality be identical. These clauses should also be in the chronological order in which the different matters to which they relate will present themselves to prospective bidders, and all clauses relating, or interrelating, to a particular subject should be grouped. One of the great troubles with specifications is that the general clauses are scattered thruout the specifications, and very often a particular clause is repeated several times. The following Standard General Clauses for the Specifications for the Department of Public Works of Philadelphia were compiled in 1915 by a committee composed of George S. Webster, Chief of Bureau of Surveys; Carlton E. Davis, Chief of Bureau of Water; and W. H. Connell, Chief of Bureau of Highways and Street Cleaning, Chairman.

Standard General Clauses for Specifications of the Department of Public Works of Philadelphia, as adopted in 1915, are as follows:

It is understood and agreed that everything herein contained, and also the proposal or bid, are hereby made part of these specifications.

Definition of Terms. Wherever, in these specifications, the following words and expressions, or pronouns used in their stead, occur, they shall have the meanings here given: City shall mean the City of Philadelphia. Director shall mean the Director of the Department of Public Works. Engineer shall mean the Chief of the Bureau of, insert here the name of the Bureau issuing the specifications, acting directly or thru his properly authorized agents, such agents acting severally within the scope of the particular duties entrusted to them. Contractor shall mean the party of the second part to this agreement. Wherever in these specifications or upon the drawings the words directed, required, permitted, ordered, designated, prescribed, or words of like import, are used, it shall be understood that the direction, requirement, permission, order, designation, or prescription of the Engineer is intended, and similarly, the words approved, acceptable, satisfactory, or words of like import, shall mean approved by, or acceptable to or satisfactory to the Engineer, subject in each case to the final determination of the Director.

Work to be Performed. Each Bureau will insert here a general description of the work to be performed, and also a list of drawings, if any.

Qualifications of Bidders. Bidders must be responsible and capable of performing the work called for by the drawings and specifications. Bidders must carefully examine the drawings, specifications, exhibited schedules, and proposal and contract forms before submitting their proposals.

Examination of Site. Bidders must examine the location of the proposed work and make themselves acquainted with the conditions on the ground and the character of material to be encountered.

Time. Bidders will take notice that the time for the completion of the work is based upon working days, said time being fixed by the Department of Public Works and is named in the proposal form.

Proposal. All proposals must be made upon the proposal forms, which are obtained at the office of the Engineer. Proposals which contain any omissions, erasures, alterations, additions not called for, conditional bids or irregularities of any kind or proposals otherwise regular which are not accompanied by a guaranty bond or a certified check and a certificate from the Department of Law that a bidding bond has been filed or upon which the surety is not named, may be rejected as informal.

Method of Expressing Bid Prices. All bids must be written with ink in words and figures and for each item where a price is called for. In case of discrepancy the written words shall be considered as being the prices bid.

Proposal Bond. The ordinance approved May 25, 1860, requires each bidder to file in the Department of Law a bidding bond in the sum of $500, and to enclose with the proposal a certificate from the Department of Law that such a bond has been filed, but when the total amount of the bid is less than $500, no proposal bond will be required. If the bidder to whom the contract shall have been awarded shall refuse or neglect to execute the contract within 10 days after being notified so to do, the amount of the bond shall be forfeited to and retained by the City as liquidated damages for such neglect or refusal.

Naming Sureties. Every proposal must name the sureties that will be furnished on the required bonds. Contractors will not be permitted to change the sureties on the bonds submitted by them, if they are from responsible sources.

Guaranty for Execution of Contract. Each proposal must be accompanied by a guaranty bond that the bidder to whom the contract is awarded will enter into the contract. Such guaranty shall be either a bond or a certified check as stipulated in the proposal. In case a bond is called for, such bond shall be executed by a responsible surety company upon the blank form furnished for that purpose, that the bidder will, if awarded the contract, execute such contract within 10 days. In case a certified check is stipulated, such check shall be in the amount indicated in the proposal. All certified checks, except that of the successful bidder, will be returned within 3 days after the contract is awarded. When the award of the contract is deferred for a period of time longer than 10 days after the receipt of bids the certified checks will be returned, provided there is substituted a bond for an equal amount prepared in form suitable to the city solicitor. Checks of successful bidders will be returned when the contract is executed and the surety bond is filed.

Method of Submitting Proposals. Proposals should be submitted in sealed envelopes furnished with the several blank proposal forms by the Engineer. Proposals shall be

deposited in the proposal box at Room 216, City Hall, Philadelphia, Pennsylvania, until 12 o'clock noon on the date indicated in the proposal form, at which time all bids will be publically opened and read in Room 225.

Estimate of Quantities. The estimate of quantities is approximate and is stated only for the purpose of comparing bids and determining the low bidder.

Presence of Bidders. Bidders are invited to be present at the opening of bids.

Unbalanced Bids. Bids in which the prices are obviously unbalanced may be rejected.

Right to Reject Bids. The Director reserves to himself the right to reject any or all bids, as he may deem best for the interests of the City.

Time in Which to Execute Contract. The bidder to whom the award shall have been made must execute the contract within 10 days after being notified so to do by the City Solicitor.

Surety Bond. The bidder to whom the contract is awarded will be required to execute a bond for the faithful execution of the work in the sum of one-half the amount of the contract, in accordance with ordinance approved July 5, 1870.

Cancellation of Award. The Director reserves the right to cancel the award of any contract at any time before the execution of the same.

Penal Bond. In addition to the surety bond, and in accordance with an ordinance approved March 30, 1896, entitled "An Ordinance for the protection of sub-contractors, as well as persons furnishing materials and labor for the construction of buildings for the City of Philadelphia or for any other City work," also a supplement to the same approved April 8, 1909, the Contractor will be required before commencing such work, to execute penal bonds in sums as follows:

Amount of Contract	Percent of Amount of Contract
For $5 000 and less	50
Over $5 000 and less than $10 000	40
For $10 000 and less than $20 000	35
For $20 000 and less than $50 000	30
For $50 000 and less than $100 000	20
For $100 000 and less than $250 000	15
For $250 000 and upwards	10

Charges of Department of Law. The charges made by the Department of Law in connection with the preparation of bonds and contracts are fixed by Ordinance of Councils approved March 28, 1881, and are as follows:

Proposal bonds	$2 each
Other bonds, contract, penal, etc	$5 each
Contracts involving:	
$1 000 or less	$3 each
Over $1 000 and not exceeding $5 000	$5 each
Over $5 000 and not exceeding $10 000	$10 each
Over $10 000	$20 each

Laws and Ordinances. All Ordinances of the City of Philadelphia, Laws of the State of Pennsylvania and of the United States shall be observed by the Contractor. Any contract awarded under these specifications will be subject also to the provisions of the following Acts of Assembly and Ordinances of Councils: (1) Act approved June 25, 1895, and Ordinance approved Dec. 16, 1896, providing that none but citizens of the United States shall be employed in any capacity on municipal work; (2) Ordinance approved Nov. 26, 1894, and the Amendment thereto approved Dec. 28, 1895, relating to the preparation and use of stone that may enter into work done under contract with the City; (3) Ordinance approved Dec. 10, 1901, providing that competent workmen shall be employed.

Time of Commencement and Completion. The Contractor shall begin work within . . . days from the date of the notice given to that effect by the Engineer, and shall complete all work under this contract within the time specified which will be reckoned from the date of the expiration of said notice.

Patented Appliances, Products or Processes. The Contractor agrees to indemnify and save harmless the City, the Director and his assistants from all suits or actions of every nature and description brought against them, or either of them, for or on account of the use of patented appliances, products or processes.

Material Samples. No materials shall be used in the work unless conforming to the requirements of these specifications, and before any contract is awarded bidders will be required upon request of the Engineer to furnish a complete statement of the origin, composition and manufacture of all materials to be used on the work, together with samples of the same, which samples may be subjected to the tests herein provided to determine their quality and fitness for the work and must all meet such tests to the satisfaction of the Engineer. The Contractor shall furnish any additional samples when required and permit any designated representative of the Engineer to inspect any and all materials being used or desired to be used at any time before, during, or after its preparation, or while being used during the progress of the work, or after the work is completed and all such material not conforming to the requirements of the specifications, whether in place or not, shall be rejected and shall be immediately removed from the work.

Fixed Prices for Contingent Work. The attention of bidders is called to the fixed prices for contingent work given in the proposal. It is understood that all definitely anticipated incidental work will be included in the estimate of quantities, and that bid prices for such incidental work will be asked for. The Contractor will, however, be required to do at the specified fixed prices any other incidental work not included in the estimate of quantities, which may become necessary to the proper execution of the contract. Where a price is asked for on the proposal form for any such incidental work, it is also understood that the unit price bid will govern for all work of this class, even altho a fixed unit price for such work be specified, and even if the estimate of quantities be exceeded in the performance of any contract.

Additional and Contingent Work. The Contractor shall do such additional work, other than that designated in the estimate of quantities, as may be necessary in the opinion of the Engineer, to fully complete the work as planned and contemplated, and will receive in full payment for such additional work the prices shown in the proposal or in the schedule of fixed prices for contingent work, and in the same manner as if such work had been included in the original estimate of quantities. Whenever such additional work comprises or consists of work coming under the several classifications for which fixed prices are named in the schedule of fixed prices for contingent work and for which no price is included in the proposal, the work shall be done for the unit prices named therein, and it shall be agreed by any Contractor executing any contract based upon these specifications, that the unit prices named therein will be accepted as full payment for any such contingent work, and such contingent work shall be done in accordance with the latest standard specifications of the Department of Public Works. Any additional work not included in the proposal or in the schedule of fixed prices for contingent work will be done at a price to be agreed upon in writing by the Contractor and the Engineer and approved by the Director.

Special Requirements. Should any construction or condition be anticipated on any proposed work, which is not covered by these specifications, the requirements thereof will be stated on the proposal form and any such special requirements shall be considered a part of these specifications, as tho they were fully contained herein. Should any such special requirement conflict with any of the provisions of these specifications, the special requirement stated on the proposal form shall govern.

Specifications and Drawings Modified by Written Agreement. The specifications and the drawings herein referred to may be modified and changed from time to time as may be agreed in writing between the Director and the Contractor in a manner not materially affecting the substance thereof, if such changes are necessary to carry out and complete more fully and perfectly the work agreed to be done and performed. If such changes and modifications increase the expense of the work, the increased expense will be paid by the City. If such modifications and changes diminish the expense of the work, the amount of said diminution may be retained or withheld by the City. No consequential loss or profit on work not executed shall be paid to the Contractor. Should the Director and the Contractor not be able to agree upon modifications and changes deemed essential by the Director, the Director may at his option cause work involved therein to be executed under a separate contract. In such a case, the work under the original contract shall be suspended, if necessary, until the changes are completed. The Contractor shall give every facility for making these changes and will not be allowed compensation for the delay except by an extension of the time for the completion of the contract.

Equipment and Material. The character, quality and quantity of equipment shall

be such as is necessary for the proper execution of the work within the specified time limit. The Contractor shall furnish all material required, which shall be in full accordance with the specifications and the general and detailed drawings.

Competent Workmen. The Contractor shall employ only competent and efficient laborers and first-class mechanics or artisans for every kind of work, and whenever, in the opinion of the Engineer, any man is unfit to perform his task, or does his work contrary to directions, or conducts himself improperly, the Contractor must discharge him immediately and not employ him again on the work.

Prosecution of Work. The work under this contract shall be prosecuted at and from as many different points, at such times, and in such part or parts of the work, and with such force of workmen and equipment as may be ordered by the Engineer.

Drawings and Specifications to be Kept on Work. The approved drawings and a copy of the specifications shall be left constantly on the work by the Contractor.

Supervision. The work shall be at all times subject to the supervision of the Engineer and of his authorized assistants, who shall have free access and every facility at all times afforded them for inspection.

Engineer to Give Orders, Explain and Decide. To prevent all disputes and litigation, the Engineer shall in all cases determine the amount or quantity of the several kinds of the work which are to be paid for under this contract, and he shall determine all questions in relation to the work and the construction thereof, and he shall in all cases decide every question which may arise relative to the performance of the work covered by this contract on the part of the Contractor. Any doubt as to the meaning of these specifications or any obscurity as to the wording of them will be explained by the Engineer, and all directions and explanations requisite or necessary to complete, explain or make definite any of the provisions of these specifications and give them due effect, will be given by the Engineer.

Inspection. Duly authorized inspectors will be assigned to the work or each part thereof who shall perform their duties under the direction of the Engineer. The Contractor shall execute his work in the presence of the Inspector and during the working hours of the day, unless specially directed otherwise, and shall afford every facility for inspecting the materials and work at all times. The presence of the Inspector shall in nowise lessen the responsibility of the Contractor.

Examination of Work. The Engineer shall be furnished with every reasonable facility for ascertaining whether the work is in accordance with the requirements and intention of this contract, even to the extent of uncovering or taking down portions of finished work. Should the work thus exposed or examined prove satisfactory, the uncovering or taking down and the replacing of the covering, or the making good of the parts removed, shall be paid for at the contract prices for the class of work done; but should the work exposed or examined prove unsatisfactory, the uncovering, taking down, replacing and making good shall be at the expense of the Contractor. All defective work which has been condemned shall be immediately removed by the Contractor and at his expense.

Defective Work. Any materials or workmanship of inferior quality, or not in accordance with the approved plans and these specifications, brought to or incorporated in the work, shall be immediately removed by the Contractor from the vicinity or built anew; and if the directions of the Director are not complied with after written notice, the said Director shall be at liberty to remove the same at the expense of the Contractor and deduct the cost thereof from any money which may be due. Materials and workmanship may be reinspected at any time. The Contractor shall furnish all necessary facilities, should it be deemed advisable by the Director to make an examination of any work already completed. If the work be found defective in any respect, the Contractor shall defray all expenses of such examinations and of proper reconstruction. If the work be found satisfactory, the expenses will be allowed for.

Suspension of Work in Freezing Weather. Work liable to be affected by frost shall be suspended during freezing weather, unless permission for continuance be given in writing, and then only for such times and under such conditions as may be specified. Upon suspension, the work shall be covered and protected as directed.

Personal Attention of Contractor. The Contractor shall be responsible for the entire work until it is completed and accepted by final payment. He shall give his personal supervision to the faithful prosecution of the work; he shall not sub-let or assign the contract but shall keep it under his own control. In case of his absence, the Contractor

shall have a competent representative or foreman on the work, who shall receive orders and directions from the Engineer, or the Engineer's representative, and who shall have full authority from the Contractor to execute these orders without delay and to supply materials, tools and labor.

Sub-Contractors. No portion of the work shall be sub-let to any sub-contractor without first giving the Engineer due notice in writing of such intention. No Subcontractor shall be employed who is unsatisfactory to the Engineer.

Disputes Between Contractors. In case of disputes arising between Contractors on adjacent work, the decision of the Engineer shall be final and binding upon the parties affected.

Permits and Licenses. The Contractor must pay for all permits and licenses; all fees and other charges from City, County or State officers, except where otherwise particularly noted in these specifications. The Contractor will be required to take out a permit for the removal and underpinning of buildings that are to be removed or underpinned under this contract, from the Bureau of Building Inspection, and to observe all the rules and regulations of the Department of Health.

Use of Water. Permits for the use of water upon construction work may be obtained from the Chief of the Bureau of Water upon application to the Engineer and subject to the following requirements of the Bureau of Water: The Contractor shall be responsible for leaving the hydrants in perfect condition; for all damage caused in the vicinity by water leaking from hydrants, and for any damage to the water mains within a reasonable distance of the hydrants used, which may be caused by improper connection of the hydrants. He shall report to the Bureau of Water all hydrants from which water is to be taken by authority of the permit, together with the condition of the hydrant before using, and shall be responsible for leaving the hydrant in a satisfactory condition. The permit will not be effective until it is approved by the Engineer. Upon the completion of the work the Contractor will be required to obtain a certificate from the Bureau of Water that the terms of this agreement have been complied with. Should the Contractor at any time waste the water, the permit will be revoked by the Chief of the Bureau of Water. On the completion of the work for which the permit is issued, the Contractor must return to the Bureau of Water all permit cards issued for the use of fire hydrants, under a penalty of $15 for each permit. This sum to be deducted from any money due to Contractor. No charge will be made for the use of water.

Accessibility of Fire Hydrants. The fire hydrants adjacent to the work shall be kept at all times readily accessible to fire apparatus and no material or other obstruction shall be placed within 5 ft of any such hydrant.

Blasting. Blasting will not be allowed unless the Contractor first obtains a permit from the Department of Public Safety, thru the Department of Public Works, and then only on condition that all blasting powder, dynamite, etc, shall be kept in a secure and approved manner, shall be at all times under the especial care of a watchman, and that each blast shall be covered with heavy timber or mats before firing, when so directed. The City reserves the right to revoke such permit at any time. All blasting shall be done in the most careful manner, so as not to endanger life or property; the blasts shall be fired only at such times as may be permitted, and whenever directed the number and size of charges shall be reduced; no claim for loss or delay will be allowed on this account. The explosive to be used shall be subject to the approval of the Engineer. All laws and ordinances relative to the storage and use of explosives must be observed.

Use of Coal Under Boilers. The Contractor shall in all cases where steam power is employed use anthracite coal under the boilers for generating steam, and in the built up sections of the City, when required by the Engineer, shall provide electric power for operating all power-driven machinery.

Sanitary Conveniences. Necessary sanitary conveniences for the use of laborers on the work, properly secluded, shall be constructed, if required, and maintained by the Contractor, and their exclusive use strictly enforced.

Danger Signals. The Contractor shall erect and maintain all necessary barricades, red lanterns and danger signals. The lights shall be kept burning from twilight until sunrise, and a watchman shall be provided for the safety of the public. The Contractor shall observe such rules relative to signals and safeguards as the police regulations, laws and ordinances require.

Responsibility for Damages. The Contractor shall assume all responsibility for risks and casualties of every description arising out of the nature of the work, the action of the elements or unforeseen or unusual difficulties. The Contractor shall assume all blame for loss by reason of neglect or violation of state, or City ordinances or laws or regulations, loss by fire due to the work on this contract, or from any other cause and all work necessary to conform to the laws and ordinances referred to as included in these specifications.

Suits and Claims. The Contractor agrees to indemnify, defend and save harmless the City, the Director and his assistants from all suits and claims for damages, loss or injury to persons or property received or sustained, from the Contractors, his agents, or servants, in the performance of the work under this agreement. The Contractor further agrees that all or so much of the moneys due him under this agreement as may be considered necessary by the Director may be retained until all such suits or claims have been settled and satisfactory evidence to that effect furnished.

Cleaning up Site of Work. Before the work will be considered as having been completed, the site of work, streets, roads, sidewalks, buildings, and all places affected by the work, are to be thoroly cleared and left clean, free and in good order and fit for travel and other proper use.

Damages for not Completing Within Time Limit. For each working day that any work shall remain uncompleted after the time specified for the completion of the work provided for in these specifications, and the accompanying contract, the sum per day, given in the following schedule, unless otherwise specified in the proposal form, may, at the option of the Director, be deducted from moneys due the Contractor, not as a penalty, but as liquidated damages. If, however, the Contractor gives the Director a satisfactory reason accounting for the delay, the Director may, in his discretion, extend the time for the completion of the work.

Amount of Contract	Amount of Liquidated Damages per Day
$5 000 and less	$5
Over $5 000 and less than $10 000	$10
$10 000 and less than $20 000	$15
$20 000 and less than $50 000	$20
$50 000 and less than $100 000	$25
$100 000 and over	Special Damages

Cancellation of Contract. The Contractor shall not be required to proceed with the work of any contract, if for any reason, for which he is not responsible, the work cannot be commenced within 6 months from the date of execution of the contract, and in such case, at the request of the Contractor, the contract may be declared null and void.

Violation of Contract. Should the work not be completed at the specified time, or should the Contractor neglect or abandon the work, or should the Director be convinced that the work is unreasonably delayed, or that the conditions of the contract are being wilfully violated or executed carelessly or in bad faith, the said Director may notify the Contractor, in writing, and if his notification be without effect within 24 hr after the delivery thereof, then, and in that case, the Contractor shall discontinue all work under the contract, and the Director shall have full authority and power to immediately purchase and hire materials, tools, labor and machinery for the completion of the contract at the expense of the Contractor, or his sureties, or both, and any moneys due the Contractor may be used for this purpose; or the said Director may declare the contract null and void, and the security, bond and retained percentage, and the materials built into the work, and the materials delivered, and the Contractor's plant, shall then become the property of the City of Philadelphia.

Scope of Payments. The Contractor shall receive and accept the assessment bills and warrants at the prices and rates respectively named therefor in the contract as full compensation for furnishing all materials, labor, tools and equipment and for doing all the work contemplated and embraced in these specifications. Note: Here should be added such detailed information as may be necessary to specifically provide for the requirements of each of the several bureaus.

Current Estimates. At intervals of about 4 weeks during the progress of the work, the Engineer will make an estimate of the value of the work done and materials incorporated in the work, and 90% of such estimated value, when approved by the

Director, will be paid to the Contractor in warrants drawn on the City Treasurer, which the Contractor agrees to accept as cash. The current monthly estimates and payments shall not bind the City to the acceptance of any materials furnished or work done. The Contractor shall not be entitled to demand or receive payment for any work as extra work unless ordered, in writing, by the Engineer to do the same as such, and at a price approved by the Director previous to its commencement.

Final Payment. After the work embraced within the contract has been completed in accordance with these specifications, the balance due the Contractor, after all legal and equitable deductions, shall be paid him, upon the acceptance and approval of the Director.
